Technically, the margin of error is defined as the radius or the half-width of a symmetric confidence interval. To formalize this definition, suppose that the targeted population parameter is denoted by θ . Let $\hat{\theta}$ represent an estimator of θ based on the sample data. Let $SD(\hat{\theta})$ denote the standard deviation of $\hat{\theta}$ (if known) or an estimator of the standard deviation (if unknown). $SD(\hat{\theta})$ is often referred to as the *standard error*.

Suppose that the sampling distribution of the standardized statistic

$$\frac{(\hat{\theta} - \theta)}{SD(\hat{\theta})}$$

is symmetric about zero. Let $Q(0.975)$ denote the 97.5th percentile of this distribution. (Note that the 2.5th percentile of the distribution would then be given by $-Q(0.975)$.) A symmetric 95% confidence interval for θ is defined as $\hat{\theta} \pm Q(0.975) SD(\hat{\theta})$. The half-width or radius of such an interval, $ME = Q(0.975)SD(\hat{\theta})$, defines the conventional margin of error, which is implicitly based on a 95% confidence level.

A more general definition of the margin of error is based on an arbitrary confidence level. Suppose $100(1 - \alpha)\%$ represents the confidence level corresponding to a selected value of α between 0 and 1.

Let $Q(1 - \frac{\alpha}{2})$ denote the $100(1 - \frac{\alpha}{2})$ th percentile of the

sampling distribution of $\frac{(\hat{\theta} - \theta)}{SD(\hat{\theta})}$. A symmetric $100(1 - \alpha)\%$ confidence interval is given by

$$\hat{\theta} \pm Q\left(1 - \frac{\alpha}{2}\right),$$

leading to a margin of error of

$$ME(\alpha) = Q\left(1 - \frac{\alpha}{2}\right) SD(\hat{\theta}).$$

The size of the margin of error is based on three factors: (1) the size of the sample, (2) the variability of the data being sampled from the population, and (3) the confidence level (assuming that the conventional 95% level is not employed). The sample size and the population variability are both reflected in the standard error of the estimator, $SD(\hat{\theta})$, which decreases as the sample size increases and grows in accordance with the dispersion of the population data. The confidence level is represented by the percentile of the sampling distribution, $Q(1 - \frac{\alpha}{2})$. This percentile becomes larger as α is decreased and the corresponding confidence level $100(1 - \alpha)\%$ is increased.

A common problem in research design is sample size determination. In estimating a parameter θ , an investigator often wishes to determine the sample size n required to ensure that the margin of error does not exceed some predetermined bound B ; that is, to find the n that will ensure $ME(\alpha) \leq B$. Solving this problem requires specifying the confidence level as well as quantifying the population variability. The latter is often accomplished by relying on data from pilot or preliminary studies, or from prior studies that investigate similar phenomena. In some instances (such as when the parameter of interest is a proportion), an upper bound can be placed on the population variability. The use of such a bound results in a conservative sample size determination; that is, the resulting n is at least as large as (and possibly larger than) the sample size actually required to achieve the desired objective.

Two of the most basic problems in statistical inference consist of estimating a population mean and estimating a population proportion under random sampling with replacement. The margins of error for these problems are presented in the next sections.

Margin of Error for Means

Assume that a random sample of size n is drawn from a quantitative population with mean μ and standard deviation σ . Let $\bar{x}$ denote the sample mean. The standard error of $\bar{x}$ is then given by

$$\frac{\sigma}{\sqrt{n}}.$$

Assume that either (a) the population data may be viewed as normally distributed or (b) the sample size is “large” (typically, 30 or greater). The sampling distribution of the standardized statistic

$$(\bar{x} - \mu) \left(\frac{\sigma}{\sqrt{n}} \right)$$

then corresponds to the standard normal distribution, either exactly (under normality of the population) or approximately (in a large sample setting, by virtue of the central limit theorem). Let $Z(1 - \frac{\alpha}{2})$ denote the $100(1 - \frac{\alpha}{2})$ th percentile of this distribution. The margin of error for $\bar{x}$ is then given by

$$ME(\alpha) = Z\left(1 - \frac{\alpha}{2}\right) \left(\frac{\sigma}{\sqrt{n}} \right).$$

With the conventional 95% confidence level, $\alpha = 0.05$ and $Z(0.975) = 1.96 \approx 2$, leading to $ME = 2 \left(\frac{\sigma}{\sqrt{n}} \right)$.

In research design, the sample size needed to ensure that the margin of error does not exceed some bound B is determined by finding the smallest n that will ensure

$$n \geq \left(Z\left(1 - \frac{\alpha}{2}\right) \frac{\sigma}{B} \right)^2.$$

In instances in which the population standard deviation σ cannot be estimated based on data collected from earlier studies, a conservative approximation of σ can be made by taking one fourth the plausible range of the variable of interest (i.e., $\left(\frac{1}{4} \right)$ [maximum–minimum]).

The preceding definition for the margin of error assumes that the standard deviation σ is known, an assumption that is unrealistic in practice. If σ is unknown, it must be estimated by the sample standard deviation s . In this case, the margin of error is based on the sampling distribution of the statistic

$$\frac{(\bar{x} - \mu)}{\left(\frac{s}{\sqrt{n}} \right)}.$$

This sampling distribution corresponds to the Student's t distribution, either exactly (under normality of the population) or approximately (in a large sample

setting). If $T_{df}(1 - \frac{\alpha}{2})$ denotes the $100(1 - \frac{\alpha}{2})$ th percentile of the t distribution with $df = n - 1$ degrees of freedom, then the margin of error for $\bar{x}$ is given by

$$ME(\alpha) = T_{df}\left(1 - \frac{\alpha}{2}\right)\left(\frac{s}{\sqrt{n}}\right).$$

Margin of Error for Proportions

Assume that a random sample of size n is drawn from a qualitative population where π denotes a proportion based on a characteristic of interest. Let p denote the sample proportion. The standard error of p is then given by

$$\frac{\pi(1 - \pi)}{n}.$$

Here, $\sqrt{\pi(1 - \pi)}$ represents the standard deviation of the binary (0/1) population data, in which each object is dichotomized according to whether it exhibits the characteristic in question. The sample version of the standard error is

$$\frac{p(1 - p)}{n}.$$

Assume that the sample size is “large” (typically, such that $n\pi$ and $n(1 - \pi)$ are both at least 10). The sampling distribution of the standardized statistic

$$\frac{(p - \pi)}{\left(\sqrt{\frac{\pi(1 - \pi)}{n}}\right)}$$

can then be approximated by the standard normal distribution. The margin of error for $\bar{x}$ is then given by

$$ME(\alpha) = Z\left(1 - \frac{\alpha}{2}\right)\left(\sqrt{\frac{p(1 - p)}{n}}\right).$$

With the conventional 95% confidence level,

$$ME = 2\left(\sqrt{\frac{p(1 - p)}{n}}\right).$$

In research design for sample size determination, for applications in which no data exist from previous studies for estimating the proportion of interest, the computation is often based on bounding the population standard deviation $\sqrt{\pi(1 - \pi)}$. Using calculus, it can be shown that this quantity achieves a maximum value of 1/2 when the proportion π is 1/2. The maximum margin of error is then defined as

$$ME_{MAX}(\alpha) = Z\left(1 - \frac{\alpha}{2}\right)\left(\frac{1}{2\sqrt{n}}\right).$$

The sample size needed to ensure that this margin of error does not exceed some bound B is determined by

$$\text{finding the smallest } n \text{ that will ensure } n \geq \left(\frac{Z(1 - \frac{\alpha}{2})}{2B}\right)^2.$$

Often in public opinion polls and other surveys, a number of population proportions are estimated, and a single margin of error is quoted for the entire set of estimates. This is generally accomplished with the preceding maximum margin of error $ME_{MAX}(\alpha)$, which is guaranteed to be at least as large as the margin of error for any of the individual estimates in the set. When the conventional 95% confidence level is employed, the maximum margin of error has a particularly simple form:

$$ME_{MAX} = \frac{1}{\sqrt{n}}.$$

National opinion polls are often based on a sample size of roughly 1,100 participants, leading to the margin of error $ME_{MAX} \approx 0.03$, or 3 percentage points.

Finite Population Correction

The preceding formulas for margins of error are based on the assumption that the sample is drawn from the population at random with replacement. If the sample is drawn at random without replacement, and the sampling fraction is relatively high (e.g., 5% or more), the formulas should be adjusted by a *finite population correction* (fpc). If N denotes the size of the population, this correction is given as

$$\text{fpc} = \frac{(N - n)}{(N - 1)}.$$

Employing this correction has the effect of reducing the margin of error. As n approaches N , the fpc becomes smaller. When $N = n$, the entire population is sampled. In this case, the fpc and the margin of error are zero because the sample estimate is equal to the population parameter and there is no estimation error. In practice, the fpc is generally ignored because the size of the sample is usually small relative to the size of the population.

Generalization to Two Parameters

The preceding definitions for the margin of error are easily generalized to settings in which two targeted population parameters are of interest, say θ_1 and θ_2 . Two parameters are often compared by estimating their

difference, say $\theta_1 - \theta_2$. Let $\hat{\theta}_1$ and $\hat{\theta}_2$ represent estimators of θ_1 and θ_2 based on the sample data. Let $SD(\hat{\theta}_1 - \hat{\theta}_2)$ denote the standard error of the difference in the estimators $\hat{\theta}_1 - \hat{\theta}_2$.

Confidence intervals for $\theta_1 - \theta_2$ may be based on the standardized statistic

$$\frac{(\hat{\theta}_1 - \hat{\theta}_2) - (\theta_1 - \theta_2)}{SD(\hat{\theta}_1 - \hat{\theta}_2)}.$$

As before, suppose that the sampling distribution of this statistic is symmetric about zero, and let $Q(0.975)$ denote the 97.5th percentile of this distribution. A symmetric 95% confidence interval for θ is defined as

$$(\hat{\theta}_1 - \hat{\theta}_2) \pm Q(0.975)SD(\hat{\theta}_1 - \hat{\theta}_2).$$

The half-width or radius of such an interval, $ME = Q(0.975)SD(\hat{\theta}_1 - \hat{\theta}_2)$, defines the conventional margin of error for the difference $\hat{\theta}_1 - \hat{\theta}_2$, which is based on a 95% confidence level. The more general definition based on an arbitrary confidence level $100(1 - \alpha)\%$ may be obtained by replacing the 97.5th percentile $Q(0.975)$ with the $100(1 - \frac{\alpha}{2})$ th percentile $Q(1 - \frac{\alpha}{2})$, leading to

$$ME(\alpha) = Q\left(1 - \frac{\alpha}{2}\right)SD(\hat{\theta}_1 - \hat{\theta}_2).$$

MARKOV CHAINS

The topic of Markov chains is a well-developed topic in probability. There are many fine expositions of Markov chains (e.g., Bremaud, 2008; Feller, 1968; Hoel, Port, & Stone, 1972; Kemeny & Snell, 1960). Those

expositions and others have informed this concise entry on Markov chains, which is not intended to exhaust the topic of Markov chains. The topic is just too capacious for that. This entry provides an exposition of a judicious sampling of the major ideas, concepts, and methods regarding the topic.

Andrei Andreevich Markov

Andrei Andreevich Markov (1856–1922) formulated the seminal concept in the field of probability later known as the Markov chain. Markov was an eminent Russian mathematician who served as a professor in the Academy of Sciences at the University of St. Petersburg. One of Markov's teachers was Pafnuty Chebyshev, a noted mathematician who formulated the famous inequality termed the *Chebyshev inequality*, which is extensively used in probability and statistics. Markov was the first person to provide a clear proof of the central limit theorem, a pivotal theorem in probability and statistics that indicates that the sum of a large number of independent random variables is asymptotically distributed as a normal distribution.

Markov was a well-trained mathematician who after 1900 emphasized inquiry in probability. After studying sequences of independent chance events, he became interested in sequences of mutually dependent events. This inquiry led to the creation of Markov chains.

Sequences of Chance Events

Markov chains are sequences of chance events. A series of flips of a fair coin is a typical sequence of chance events. Each coin flip has two possible outcomes: Either a head (H) appears or a tail (T) appears. With a fair coin, a head will appear with a probability (p) of $1/2$ and a tail will appear with a probability of $1/2$.

Successive coin flips are independent of each other in the sense that the probability of a head or a tail on the first flip does not affect the probability of a head or a tail on the second flip. In the case of the sequence HT , the $p(HT) = p(H) \times p(T) = 1/2 \times 1/2 = 1/4$. Many sequences of chance events are composed of independent chance events such as coin flips or dice throws. However, some sequences of chance events are not composed of independent chance events. Some sequences of chance events are composed of events whose occurrences are influenced by prior chance events. Markov chains are such sequences of chance events.

As an example of a sequence of chance events that involves interdependence of events, let us consider a sequence of events E_1, E_2, E_3, E_4 such that the probability

of any of the events after E_1 is a function of the prior event. Instead of interpreting the $p(E_1, E_2, E_3, E_4)$ as the product of probabilities of independent events, $p(E_1, E_2, E_3, E_4)$ is the product of an initial event probability and the conditional probabilities of successive events. From this perspective,

$$p(E_1, E_2, E_3, E_4) = p(E_1) \times p(E_2 | E_1) \times p(E_3 | E_2) \times p(E_4 | E_3).$$

Such a sequence of events is a Markov chain.

Let us consider a sequence of chance events $E_1, E_2, E_3, \dots, E_j, \dots, E_n$. If $p(E_j | E_{j-1}) = p(E_j | E_{j-1}, E_{j-2}, \dots, E_1)$, then the sequence of chance events is a Markov chain. For a more formal definition, if $X_1, X_2, \dots, X_n$ are random variables and if $p(X_n = k_n | X_{n-1} = k_{n-1}) = p(X_n = k_n | X_{n-1} = k_{n-1}, \dots, X_2 = k_2, X_1 = k_1)$, then $X_1, X_2, \dots, X_n$ form a Markov chain.

Conditional probabilities interrelating events are important in defining a Markov chain. Common in expositions of Markov chains, conditional probabilities interrelating events are termed *transition probabilities interrelating states*, events are termed *states*, and a set of states is often termed a *system* or a *state space*. The states in a Markov chain are either finite or countably infinite; this entry will feature systems or state spaces whose states are finite in number.

A matrix of *transition probabilities* is used to represent the interstate transitions possible for a Markov chain. As an example, consider the following system of states, S_1, S_2 , and S_3 , with the following matrix of transition probabilities, P_1 .

$$P_1 = \begin{matrix} & \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{matrix} S_1 \\ S_2 \\ S_3 \end{matrix} & \begin{bmatrix} .1 & .8 & .1 \\ .5 & .3 & .2 \\ .1 & .7 & .2 \end{bmatrix} \end{matrix}$$

Using the matrix P_1 , one can see that the transition probability of entering S_1 given that one is in S_2 is .8. That same probability is represented as p_{12} .

Features of Markov Chains and Their States

There are various types of states in a Markov chain. Some types of states in a Markov chain relate to the degree to which states recur over time. A *recurrent state* is one that will return to itself before an infinite number of steps with probability 1. An *absorbing state* i is a recurrent state for which $p_{ii} = 1$ and $p_{ij} = 0$ for $i \neq j$. In other words, if it is not possible to leave a given state, then that state is an absorbing state. Second, a state is *transient* if it is not recurrent. In other words, if the probability that a state will occur again before an

infinite number of steps is less than 1, then that state is transient.

To illustrate the attributes of absorbing and transient states, let us consider the following example. A type of job certification involves a test with three resulting states. With state S_1 , one fails the test with a failing score and then maintains that failure status. With state S_2 , one passes the test with a low pass score that is inadequate for certification. One then takes the test again. Either one attains state S_2 again with a probability of .5 or one passes the test with a high pass score and reaches state S_3 with a probability of .5. With state S_3 , one passes the test with a high pass score that warrants job certification.

$$P_1 = \begin{matrix} & \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{matrix} S_1 \\ S_2 \\ S_3 \end{matrix} & \begin{bmatrix} 1 & 0 & 0 \\ 0 & .5 & .5 \\ 0 & 0 & 1 \end{bmatrix} \end{matrix}$$

P_1 indicates the transition probabilities among the three states of the job certification process. From an examination of P_1 , state S_1 is an absorbing state because $p_{11} = 1$ and $p_{1j} = 0$ for $1 \neq j$, and state S_3 is an absorbing state because $p_{33} = 1$ and $p_{3j} = 0$ for $3 \neq j$. However, state S_2 is a transient state because there is a nonzero probability that the state will never be reached again.

To illustrate that state S_2 will never be reached again, let us examine what happens as the successive steps in the Markov chain occur. P_1 indicates the transition probabilities among the three states of the job certification process. P_1^2 indicates the transition probabilities after two steps in the process.

$$P_1^2 = \begin{matrix} & \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{matrix} S_1 \\ S_2 \\ S_3 \end{matrix} & \begin{bmatrix} 1 & 0 & 0 \\ 0 & .25 & .75 \\ 0 & 0 & 1 \end{bmatrix} \end{matrix}$$

After two steps, p_{22} has decreased to .25 and p_{23} has increased to .75. P_1^3 indicates the transition probabilities after two steps in the process.

$$P_1^3 = \begin{matrix} & \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{matrix} S_1 \\ S_2 \\ S_3 \end{matrix} & \begin{bmatrix} 1 & 0 & 0 \\ 0 & .06 & .94 \\ 0 & 0 & 1 \end{bmatrix} \end{matrix}$$

After three steps, p_{22} has further decreased to .06 and p_{23} has further increased to .94. One could surmise that p_{22} will further decrease and p_{23} will further decrease as the number of steps increases. P_1^2 and P_1^3

suggest that those receiving an intermediate score will pass the test with successive attempts.

Generalizing to n steps, $\mathbf{P}_2^n$ indicates the transition probabilities after n steps in the process.

$$\mathbf{P}_2^n = \begin{matrix} & \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{matrix} S_1 \\ S_2 \\ S_3 \end{matrix} & \begin{bmatrix} 1 & 0 & 0 \\ 0 & (.5)^n & 1 - (.5)^n \\ 0 & 0 & 1 \end{bmatrix} \end{matrix}$$

As n increases, p_{22} will approach 0 and p_{23} will approach 1. From an examination of $\mathbf{P}_2^n$, it is clear that those receiving an intermediate score will inexorably pass the test with successive attempts at taking the test. As the number of steps in the process increases, individuals will either have failed the job certification procedure or have passed the job certification procedure.

Additional types of states in a Markov chain relate to the degree to which states can be reached from other states in the chain. A state i is *accessible* from a different state j if there is a nonzero probability that state j can be reached from state i some time in the future. Second, a state i *communicates* with state j if state i is accessible from state j and state j is accessible from state i . A set of states in a Markov chain is a *communicating class* if every pair of states in the set communicates with each other. A communicating class is *closed* if it is not possible to reach a state outside the class from a state within the class. A Markov chain is *irreducible* if any state within the chain is accessible from any other state in the chain. An irreducible Markov chain is also termed an *ergodic* Markov chain.

To illustrate these attributes, let us consider the following Markov chain and its transition probability matrix. This hypothetical chain describes the transition from the IQ of the parent to the IQ of a child of the parent. Let the states be three levels of IQ: high, intermediate, and low. $\mathbf{P}_3$ is the transition matrix for this Markov chain.

$$\begin{array}{c} \text{Child IQ} \\ \begin{matrix} S_1 & S_2 & S_3 \\ \text{Parental IQ (low) (intermediate) (high)} \end{matrix} \end{array}$$

$$\mathbf{P}_3 = \begin{matrix} S_1 \text{ (low)} \\ S_2 \text{ (intermediate)} \\ S_3 \text{ (high)} \end{matrix} \begin{bmatrix} .6 & .3 & .1 \\ .2 & .6 & .2 \\ .1 & .3 & .6 \end{bmatrix}$$

The Markov chain indicated by $\mathbf{P}_3$ reflects the view that the IQ of the parent tends to determine the IQ of the child.

All the states in $\mathbf{P}_3$ are accessible from each other, and they all communicate with each other. Thus the states in $\mathbf{P}_3$ form a communicating class. In addition, this Markov chain is irreducible and ergodic.

But what would be the probabilities of the three levels of parental IQ if this Markov chain would proceed for many steps? To determine these probabilities, also called *stationary* probabilities, one needs to use an important finding in the study of Markov chains.

Let us assume that we have a transition probability matrix, $\mathbf{P}$, which, for some n , $\mathbf{P}^n$ has only nonzero entries. Then $\mathbf{P}$ is termed a *regular* matrix. Then two prominent theorems follow.

The first theorem addresses the increasing similarity of rows in successive powers of $\mathbf{P}$. If $\mathbf{P}$ is a regular transition probability matrix, then $\mathbf{P}^n$ becomes increasingly more similar to a probability matrix Π with each row of Π being the same probability vector $\pi = (\pi_1, \pi_2, \dots, \pi_k)$ and with the components of π being positive.

The second theorem indicates the equation that permits the computation of stationary probabilities. If $\mathbf{P}$ is a regular transition probability matrix, then the row vector π is the unique vector of probabilities that satisfies the equation $\pi = \pi \cdot \mathbf{P}$. This theorem is one of the more important theorems in the study of Markov chains.

With the equation $\pi = \pi \cdot \mathbf{P}$, we can determine the stationary probabilities for $\mathbf{P}_3$. Let $\pi_3 = (\pi_{31}, \pi_{32}, \pi_{33})$ be the vector of stationary probabilities for this three-state Markov chain associated with $\mathbf{P}_3$. Then $\pi_3 = \pi_3 \cdot \mathbf{P}_3$.

$$\begin{aligned} (\pi_{31}, \pi_{32}, \pi_{33}) &= (\pi_{31}, \pi_{32}, \pi_{33}) \cdot \begin{bmatrix} .6 & .3 & .1 \\ .2 & .6 & .2 \\ .1 & .3 & .6 \end{bmatrix} \\ &= (.6\pi_{31} + .2\pi_{32} + .1\pi_{33}, .3\pi_{31} + .6\pi_{32} \\ &\quad + .3\pi_{33}, .1\pi_{31} + .2\pi_{32} + .6\pi_{33}) \end{aligned}$$

This results in three equations:

$$(1) \pi_{31} = .6\pi_{31} + .2\pi_{32} + .1\pi_{33}$$

$$(2) \pi_{32} = .3\pi_{31} + .6\pi_{32} + .3\pi_{33}$$

$$(3) \pi_{33} = .1\pi_{31} + .2\pi_{32} + .6\pi_{33}$$

Along with those three equations is the additional equation:

$$(4) \pi_{31} + \pi_{32} + \pi_{33} = 1.$$

An arithmetic manipulation of these four equations results in numerical solutions for the three unknowns: $\pi_{31} = 2/7 = .286$, $\pi_{32} = 3/7 = .428$, and $\pi_{33} = 2/7 = .286$.

= .286. These three stationary probabilities indicate that there would be a modest trend toward intermediate IQs over many generations.

Let us consider another Markov chain and its transition probability matrix. This hypothetical chain also describes the transition from the IQ of the parent to the IQ of a child of the parent. Let the states again be three levels of IQ: high, intermediate, and low. P_4 is the transition matrix for this Markov chain.

$$\begin{array}{c} \text{Child IQ} \\ \begin{array}{ccc} S_1 & S_2 & S_3 \end{array} \\ \text{Parental IQ (low) (intermediate) (high)} \end{array}$$

$$P_4 = \begin{array}{c} S_1 \text{ (low)} \\ S_2 \text{ (intermediate)} \\ S_3 \text{ (high)} \end{array} \begin{bmatrix} .4 & .4 & .2 \\ .3 & .4 & .3 \\ .2 & .4 & .4 \end{bmatrix}$$

The Markov chain indicated by P_4 reflects the view that the IQ of the parent weakly influences the IQ of the child.

What would be the probabilities of the three levels of parental IQ if this Markov chain would proceed for many steps? To determine these probabilities, also called stationary probabilities, one needs to solve the equation $\pi_4 = \pi_4 \cdot P_4$ with $\pi_4 = (\pi_{41}, \pi_{42}, \pi_{43})$, the vector of stationary probabilities for this three-state Markov chain.

$$\begin{aligned} & \begin{bmatrix} .4 & .4 & .2 \\ .3 & .4 & .3 \\ .2 & .4 & .4 \end{bmatrix} \\ & = (.4\pi_{41} + .3\pi_{42} + .2\pi_{43}, .4\pi_{41} + .4\pi_{42} + .4\pi_{43}, .2\pi_{41} \\ & \quad + .3\pi_{42} + .4\pi_{43}) \end{aligned}$$

This results in three equations:

$$\begin{aligned} (1) \quad \pi_{41} &= .4\pi_{41} + .3\pi_{42} + .2\pi_{43} \\ (2) \quad \pi_{42} &= .4\pi_{41} + .4\pi_{42} + .4\pi_{43} \\ (3) \quad \pi_{43} &= .2\pi_{41} + .3\pi_{42} + .4\pi_{43} \end{aligned}$$

Along with those three equations is the additional equation:

$$(4) \quad \pi_{41} + \pi_{42} + \pi_{43} = 1.$$

An arithmetic manipulation of these four equations results in numerical solutions for the three unknowns: $\pi_{41} = 3/10 = .3$, $\pi_{42} = 2/5 = .4$, and $\pi_{43} = 3/10 = .3$. These three stationary probabilities indicate that there

would be a weak trend toward intermediate IQs over many generations with this Markov chain but not as strong a trend as with the prior Markov chain depicted with P_3 .

Not all Markov chains have unique stationary probabilities. Let us consider the matrix of transition probabilities, P_2 , with two absorbing states.

$$\begin{array}{c} S_1 \quad S_2 \quad S_3 \\ P_2 = \begin{array}{c} S_1 \\ S_2 \\ S_3 \end{array} \begin{bmatrix} 1 & 0 & 0 \\ 0 & .5 & .5 \\ 0 & 0 & 1 \end{bmatrix} \end{array}$$

To determine the stationary probabilities, one needs to solve the equation: $\pi_2 = \pi_2 \cdot P_2$ with $\pi_2 = (\pi_{21}, \pi_{22}, \pi_{23})$, the vector of stationary probabilities for this three-state Markov chain

$$\begin{aligned} (\pi_{21}, \pi_{22}, \pi_{23}) &= (\pi_{21}, \pi_{22}, \pi_{23}) \cdot \begin{bmatrix} 1 & 0 & 0 \\ 0 & .5 & .5 \\ 0 & 0 & 1 \end{bmatrix} \\ &= (\pi_{21}, .5\pi_{22} + .5\pi_{23}, .5\pi_{22} + .5\pi_{23}) \end{aligned}$$

This results in three equations:

$$\begin{aligned} 1. \quad \pi_{21} &= \pi_{21} \\ 2. \quad \pi_{22} &= .5\pi_{22} + .5\pi_{23} \\ 3. \quad \pi_{23} &= .5\pi_{22} + .5\pi_{23} \end{aligned}$$

Along with those three equations is the additional equation:

$$4. \quad \pi_{21} + \pi_{22} + \pi_{23} = 1.$$

An arithmetic manipulation of these 4 equations results in numerical solutions for the three unknowns: $\pi_{21} = 1 - \pi_{23}$, $\pi_{22} = 0$, and $\pi_{23} = 1 - \pi_{21}$. These three stationary probabilities indicate that there could be an infinite number of values for π_{21} and π_{23} .

Additional types of states in a Markov chain relate to the rates at which states in the Markov chain return to themselves over time. If there is a return to state i starting from state i after every three steps, then state i has a *period* of 3. In general, if there is a return to a given state in a Markov chain after every t steps if one starts with that state, then that state is periodic with period t . A state is recurrent or persistent if there is a probability of 1 that the state will be reached again.

To illustrate these attributes, let us consider the following example. Let P_5 be a matrix of transition probabilities for a Markov chain with three absorbing states.

$$P_5 = \begin{matrix} & \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{matrix} S_1 \\ S_2 \\ S_3 \end{matrix} & \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix} \end{matrix}$$

After one step in the Markov chain, P_5^2 indicates the resulting transition probabilities.

$$P_5^2 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

P_5^3 is the identity matrix. After two steps in the Markov chain, P_5^3 indicates the resulting transition probabilities.

$$P_5^3 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}$$

$P_5^3 = P_5$. One could then generalize to the following equality: $P_5^{2n+1} = P_5$ with n = any natural number. Regarding the attributes of periodicity or recurrence, state S_{11} is recurrent at each step and states S_{13} and S_{32} are periodic with period 2.

One type of Markov chain that is commonplace among expositions of Markov chains is that of the random walk. Imagine a person named Harry, a frequent visitor to a bar, planning to leave the bar, represented as state S_2 . From the bar, Harry could start walking to his home and return to the bar, S_1 , or walk to a park, state S_3 , that is halfway between the bar and his home. If Harry is at the park, state S_3 , then he could start walking to his home and return to the park or walk to his home, state S_1 . If Harry is at his home, then Harry could remain at his home or walk to the park. P_6 is the matrix of transition probabilities that relates to this random walk.

$$P_6 = \begin{matrix} & \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{matrix} S_1 \text{ (bar)} \\ S_2 \text{ (park)} \\ S_3 \text{ (home)} \end{matrix} & \begin{bmatrix} .5 & .5 & 0 \\ .5 & 0 & .5 \\ 0 & .5 & .5 \end{bmatrix} \end{matrix}$$

To determine the stationary probabilities, one needs to solve the equation: $\pi_6 = \pi_6 \cdot P_6$ with $\pi_6 = (\pi_{61}, \pi_{62}, \pi_{63})$, the vector of stationary probabilities for this three-state Markov chain.

$$\begin{aligned} (\pi_{61}, \pi_{62}, \pi_{63}) &= (\pi_{61}, \pi_{62}, \pi_{63}) \cdot \begin{bmatrix} .5 & .5 & 0 \\ .5 & 0 & .5 \\ 0 & .5 & .5 \end{bmatrix} \\ &= (.5\pi_{61} + .5\pi_{62}, .5\pi_{61} + .5\pi_{63}, .5\pi_{62} + .5\pi_{63}) \end{aligned}$$

This results in three equations:

$$1. \pi_{61} = .5\pi_{61} + .5\pi_{62}$$

$$2. \pi_{62} = .5\pi_{61} + .5\pi_{63}$$

$$3. \pi_{63} = .5\pi_{62} + .5\pi_{63}$$

Along with those three equations is the additional equation

$$4. \pi_{61} + \pi_{62} + \pi_{63} = 1.$$

An arithmetic manipulation of these four equations results in numerical solutions for the three unknowns: $\pi_{61} = \pi_{62} = \pi_{63} = 1/3 = .33$. These stationary probabilities indicate that Harry would be at any of the three locations with equal likelihood after many steps in the random walk.

Conclusion

If there is a sequence of random events such that a future event is dependent only on the present event and not on past events, then the sequence is likely a Markov chain, and the work of Markov and others may be used to extract useful information from an analysis of the sequence. The topic of the Markov chain has become one of the most captivating, generative, and useful topics in probability and statistics.

MASKING

Masking (or blinding) is a design technique used to minimize bias in clinical trials with more than one trial arm. It refers to the process in which one or more parties involved in the trial, such as participants or investigators, are withheld the knowledge about the treatment type assignment. Masking is used to conceal

the treatment identity during its administration. It protects against the disclosure (e.g., by appearance, smell, taste, route of administration) of whether a trial participant is receiving an experimental treatment, an active comparator, or a placebo. The aim of masking is to ensure that all participants are treated in the same manner throughout the trial and personal expectations or preferences related to the treatment type do not influence the trial results. It is a favorable feature of any clinical trial used to ensure the objectivity and maximize the validity of the results. This entry provides general characteristics of masking procedure with a discussion about levels and importance in clinical trials.

Masking, Blinding, and Allocation Concealment

Most researchers use the terms “masking” and “blinding” interchangeably, but “blinding” seems to be more popular in clinical trial environments and is usually mentioned first in many clinical trial guidelines. However, some researchers, such as those who work in ophthalmology, advise the use of “masking” rather than “blinding,” because some participants may interpret “blinding” to mean they will lose their eyesight. Sometimes “masking” is defined as the method of how interventions are made indistinguishable, whereas “blinding” refers to which groups are withheld knowledge about treatment assignments. Although these two terms usually are generally considered equivalent, there are some doubts about which one is more appropriate when referencing clinical trials.

However, masking is different from an allocation concealment. Allocation concealment protects against selection bias and ensures that a treatment-allocating staff member does not know who the next person will be to receive the treatment. Masking is a procedure applied after the randomization procedure, whereas allocation concealment is performed prior to randomization.

Importance of Masking in Clinical Trials

Knowledge about treatment assignment in clinical trials may generate ascertainment bias and influence an individual's behavior. For example, participants who are aware of assignment to active treatment may be more willing to follow the recommendations and treatment regimen rather than those in the placebo group. Similarly, investigators who know who receives which regimen can be affected by their own attitude to treatment effectiveness. They might believe that the new intervention is better than the old and directly transfer that belief to participants. The investigators or

participants may be too enthusiastic or pessimistic during outcome assessment, especially if the measurements in clinical trials are prone to be subjective and the assessment is based on observations and feelings (e.g., pain, quality of life) rather than objective outcomes like laboratory or diagnostic tests. This approach could affect the reliability of the trial results, which is why masking is so important. Masking allows patients and researchers to remain objective regardless of observing positive or negative effects of the treatment.

Levels of Masking

Masking can be applied to various individuals involved in a clinical trial process: (a) participants or patients; (b) investigators, health-care providers, or clinical staff; (c) outcome assessors or staff responsible for measurement; and (d) data analysts such as statisticians. Levels of masking are determined by the number of blinded parties. The most common trials are single-, double-, or triple-blinded trials. In a single-blinded trial, only one party is masked (usually, trial participants or investigators), whereas in a double-blinded trial, two parties are unaware of treatment allocation (usually, participants and investigators). Triple-blinding is often understood as masking participants, investigators, and other trial staff. Trials in which the identity of treatment is known to all involved individuals is called an *open label* (or *unblinded* or *unmasked*).

Generally, the higher the level of masking, the better for the quality of results; but the method of applying masking depends on the nature of the intervention. Sometimes it is not possible to implement masking due to some technical, methodological, or ethical reason. For example, it is easier to blind pharmacological trials rather than trials with specific therapeutic procedures (e.g., surgery, psychotherapy, physical activity). When reporting outcomes of clinical trials, researchers should always carefully describe who (if any) were masked in the clinical trial, because identifying only the level is ambiguous and uninformative. For example, in the case of a single-blinded trial, one experimenter may interpret it to mean that participants were blinded, whereas another may interpret it to mean that the investigators were blinded.

Masking Methods

With masking in clinical trials, interventions that seemingly look identical are used. For example, if a trial uses a placebo (i.e., pharmacologically inactive treatment) as comparator, the placebo is prepared to resemble the tested intervention as much as possible. Sometimes the process of masking can be more complex, especially if a

trial compares two active interventions that differ in pharmaceutical form and route of administration, such as infusion and oral tablets. In such cases, an appropriate placebo control is prepared for each intervention: Participants in one group receive active infusion and an oral placebo, whereas participants in the other group receive active oral tablet and placebo infusion (this process is also called *double dummy*). If masking is not possible to implement, bias can be minimized by using objective measurements to assess intervention effectiveness.

Unmasking and Right to Information

Eventually trials are unmasked, and many ethicists argue that participants have the right to learn in which trial arm they participated. In some cases, this information may influence participants' behavior. For example, information about whether an individual was allocated to placebo or therapy arm in a prevention trial of a successfully developed vaccine can have a great impact on an individual's behavior and risk assessment. For example, individuals believing that they participated in an active vaccine arm may be more likely to expose themselves to a pathogen, believing that they are secured by the vaccine. Thus, in general, unmasking and providing information about allocations to participants after the trial's end is encouraged. However, in some cases (e.g., trials including behavioral or social interventions), unmasking can negatively influence the placebo effect. For example, some interventions using placebo may be effective in reducing suffering because a patient believed that she or he participated in an arm of the trial that used an active intervention. Some patients are aware of the placebo effect and this may be the reason that they may not want to know the results of unmasking and their preferences should be respected (the right not to know).

MATCHING

The term *matching* refers to the procedure of finding for a sample unit other units in the sample that are closest in terms of observable characteristics. The units selected are usually referred to as *matches*, and after repeating this procedure for all units (or a subgroup of them), the resulting subsample of units is called the *matched sample*. This idea is typically implemented across subgroups of a given sample, that is, for each unit in one subgroup, matches are found among units of another subgroup. A matching procedure requires defining a notion of distance, selecting the number of matches to be found, and deciding whether units will be used multiple times as a potential match. In applications, matching is commonly used as a preliminary step in the construction of a matched sample, that is, a sample of observations that are similar in terms of observed characteristics, and then some statistical procedure is computed with this subsample. Typically, the term *matching estimator* refers to the case when the statistical procedure of interest is a point estimator, such as the sample mean. The idea of matching is usually employed in the context of observational studies, in which it is assumed that selection into treatment, if present, is based on observable characteristics. More generally, under appropriate assumptions, matching may be used as a way of reducing variability in estimation, combining databases from different sources, dealing with missing data, and designing sampling strategies, among other possibilities. Finally, in the econometrics literature, the term *matching* is sometimes used more broadly to refer to a class of estimators that exploit the idea of selection on observables in the context of program evaluation. This entry focuses on the implementation of and statistical inference procedures for matching.

Description and Implementation

A natural way of describing matching formally is in the context of the classical potential outcomes model. To describe this model, suppose that a random sample of size n is available from a large population, which is represented by the collection of random variables (Y_i, T_i, X_i) , $i = 1, 2, \dots, n$, where $T_i \in \{0, 1\}$,

$$Y_i = \begin{cases} Y_{0i} & \text{if } T_i = 0 \\ Y_{1i} & \text{if } T_i = 1 \end{cases}$$

and X_i represents a (possibly high-dimensional) vector of observed characteristics. This model aims to capture the idea that while the set of characteristics X_i

is observed for all units, only one of the two random variables (Y_{0i}, Y_{1i}) is observed for each unit, depending on the value of T_i . The underlying random variables Y_{0i} and Y_{1i} are usually referred to as potential outcomes because they represent the two potential states for each unit. For example, this model is routinely used in the program evaluation literature, where T_i represents treatment status and Y_{0i} and Y_{1i} represent outcomes without and with treatment, respectively. In most applications the goal is to establish statistical inference for some characteristic of the distribution of the potential outcomes such as the mean or quantiles. However, using the available sample directly to establish inference may lead to important biases in the estimation whenever units have selected into one of the two possible groups ($T_i = 0$ or $T_i = 1$). As a consequence, researchers often assume that the selection process, if present, is based on observable characteristics. This idea is formalized by the so-called *conditional independence assumption*: conditionally on X_i , the random variables (Y_{0i}, Y_{1i}) are independent of T_i . In other words, under this assumption, units having the same observable characteristics X_i are assigned to each of the two groups ($T_i = 0$ or $T_i = 1$) independently of their potential gains, captured by (Y_{0i}, Y_{1i}) . Thus, this assumption imposes random treatment assignment conditional on X_i . This model also assumes some form of *overlap* or *common support*: For some $c > 0$, $c \leq \mathbb{P}(T_i = 1 | X_i) \leq 1 - c$. In words, this additional assumption ensures that there will be observations in both groups having a common value of observed characteristics if the sample size is large enough. The function $p(X_i) = \mathbb{P}(T_i = 1 | X_i)$ is known as the *propensity score* and plays an important role in the literature. Finally, it is important to note that for many applications of interest, the model described above employs stronger assumptions than needed. For simplicity, however, the following discussion does not address these distinctions.

This setup naturally motivates matching: observations sharing common (or very similar) values of the observable characteristics X_i are assumed to be free of any selection biases, rendering the statistical inference that uses these observations valid. Of course, matching is not the only way of conducting correct inference in this model. Several parametric, semiparametric, and nonparametric techniques are available, depending on the object of interest and the assumptions imposed. Nonetheless, matching is an attractive procedure because it does not require employing smoothing techniques and appears to be less sensitive to some choices of user-defined tuning parameters.

To describe a matching procedure in detail, consider the special case of matching that uses the Euclidean distance to obtain $M \geq 1$ matches with replacement for the two groups of observations defined by $T_i = 0$ and $T_i = 1$, using as a reservoir of potential matches for each unit i the group opposite to the group this unit belongs to. Then, for unit i the m th match, $m = 1, 2, \dots, M$ is given by the observation having index $j_m(i)$ such that

$$T_{j_m(i)} \neq T_i \text{ and } \sum_{j=1}^n 1\{T_j \neq T_i\} 1\{\|X_j - X_i\| \leq \|X_{j_m(i)} - X_i\|\} = m.$$

(The function $1\{\cdot\}$ is the indicator function and $\|\cdot\|$ represents the Euclidean norm.) In words, for the i th unit, the m th match corresponds to the m th nearest neighbor among those observations belonging to the opposite group of unit i , as measured by the Euclidean distance between their observable characteristics. For example, if $m = 1$, then $j_1(i)$ corresponds to the unit's index in the opposite group of unit i with the property that $\|X_{j_1(i)} - X_i\| \leq \|X_j - X_i\|$ for all j such that $T_j \neq T_i$, that is, $X_{j_m(i)}$ is the observation closest to X_i among all the observations in the appropriate group. Similarly, $X_{j_1(i)}, X_{j_2(i)}, \dots, X_{j_M(i)}$ are the second closest, third closest, and so forth, observations to X_i , among those observations in the appropriate subsample. Notice that to simplify the discussion, this definition assumes existence and uniqueness of an observation with index $j_m(i)$. (It is possible to modify the matching procedure to account for these problems.)

In general, the always observed random vector X_i may include both discrete and continuous random variables. When the distribution of (a subvector of) X_i is discrete, the matching procedure may be done exactly in large samples, leading to so-called *exact matching*. However, for those components of X_i that are continuously distributed, matching cannot be done exactly, and therefore in any given sample there will be a discrepancy in terms of observable characteristics, sometimes called the *matching discrepancy*. This discrepancy generates a bias that may affect inference even asymptotically.

The M matches for unit i are given by the observations with indexes $J_M(i) = \{j_1(i), \dots, j_M(i)\}$, that is, $(Y_{j_1(i)}, X_{j_1(i)}), \dots, (Y_{j_M(i)}, X_{j_M(i)})$. This procedure is repeated for the appropriate subsample of units to obtain the final matched sample. Once the matched sample is available, the statistical procedure of interest may be computed. To this end, the first step is to “recover” those counterfactual variables not observed for each

unit, which in the context of matching is done by imputation. For example, first define

$$\hat{Y}_{0i} = \begin{cases} Y_i & \text{if } T_i = 0 \\ \frac{1}{M} \sum_{j \in J_M(i)} Y_j & \text{if } T_i = 1 \text{ and} \end{cases}$$

$$\hat{Y}_{1i} = \begin{cases} \frac{1}{M} \sum_{j \in J_M(i)} Y_j & \text{if } T_i = 0, \\ Y_i & \text{if } T_i = 1 \end{cases}$$

that is, for each unit the unobserved counterfactual variable is imputed using the average of its M matches. Then simple matching estimators are easy to construct: A matching estimator for $\mu_1 = \mathbb{E}[Y_{1i}]$, the mean of Y_{1i} is given by $\hat{\mu}_1 = \frac{1}{n} \sum_{i=1}^n \hat{Y}_{1i}$, while a matching estimator for $\tau = \mu_1 - \mu_0 = \mathbb{E}[Y_{1i}] - \mathbb{E}[Y_{0i}]$, the difference in means between both groups, is given by $\hat{\tau} = \hat{\mu}_1 - \hat{\mu}_0$, where $\hat{\mu}_0 = \frac{1}{n} \sum_{i=1}^n \hat{Y}_{0i}$. The latter estimand is called the average treatment effect in the literature of program evaluation and has received special attention in the theoretical literature of matching estimation.

Matching may also be carried out using estimated rather than observed random variables. A classical example is the so-called *propensity score matching*, which constructs a matched sample using the estimated propensity score (rather than the observed X_i) to measure the proximity between observations. Furthermore, matching may also be used to estimate other population parameters of interest, such as quantiles or dispersion measures, in a conceptually similar way. Intuitively, in all cases a matching estimator imputes values for otherwise unobserved random variables using the matched sample. This imputation procedure coincides with an M nearest neighbor ($M - NN$) nonparametric regression estimator.

The implementation of matching is based on several user-defined options (metric, number of matches, etc.), and therefore numerous variants of this procedure may be considered. In all cases, a fast and reliable algorithm is needed to construct a matched sample. Among the available implementations, the so-called *genetic matching*, which uses evolutionary genetic algorithms to construct the matched sample, appears to work well with moderate sample sizes. This implementation allows for a generalized notion of distance (a reweighted Euclidean norm that includes the Mahalanobis metric as a particular case) and an arbitrary number of matches with and without replacement.

There exist several generalizations of the basic matching procedure described above, a particularly important one being the so-called *optimal full matching*. This procedure generalizes the idea of pair or M matching by constructing multiple submatched samples that may include more than one observation from each group. This procedure encompasses the simple matching procedures previously discussed and enjoys certain demonstrable optimality properties.

Statistical Inference

In recent years, there have been important theoretical developments in statistics and econometrics concerning matching estimators for average treatment effects under the conditional independence assumption. These results establish the validity and lack of validity of commonly used statistical inference procedures involving simple matching estimators.

Despite the fact that in some cases, and under somewhat restrictive assumptions, exact (finite sample) statistical inference results for matching estimators exist, the most important theoretical developments currently available have been derived for large samples and under mild, standard assumptions. Naturally, these asymptotic results have the advantage of being invariant to particular distributional assumptions and the disadvantage of being valid only for large enough samples.

First, despite the relative complexity of matching estimators, it has been established that these estimators for averages with and without replacement enjoy root- n consistency and asymptotic normality under reasonable assumptions. In other words, the estimators described in the previous section (as well as other variants of them) achieve the parametric rate of convergence having a Gaussian limiting distribution after appropriate centering and rescaling. It is important to note that the necessary conditions for this result to hold include the restriction that at most one dimension of the observed characteristics is continuously distributed, regardless of how many discrete covariates are included in the vector of observed characteristics used by the matching procedure. Intuitively, this restriction arises as a consequence of the bias introduced by the matching discrepancy for continuously distributed observed characteristics, which turns out not to vanish even asymptotically when more than one continuous covariate are included. This problem may be fixed at the expense of introducing further bias reduction techniques that involve nonparametric smoothing procedures, making the “bias corrected” matching estimator somehow less appealing.

Second, regarding the (asymptotic) precision of matching estimators for averages, it has been shown that these estimators do not achieve the minimum possible variance, that is, these estimators are inefficient when compared with other available procedures. However, this efficiency loss is relatively small and decreases fast with the number of matches to be found for each observation.

Finally, in terms of uncertainty estimates of matching estimators for averages, two important results are available. First, it has been shown that the classical *bootstrap* procedure would provide an inconsistent estimate of the standard errors of the matching estimators. For this reason, other resampling techniques must be used, such as *m out of n bootstrap* or *subsampling*, which do deliver consistent standard error estimates under mild regularity conditions. Second, as an alternative, it is possible to construct a consistent estimator of the standard errors that does not require explicit estimation of nonparametric parameters. This estimator uses the matched sample to construct a consistent estimator of the asymptotic (two-piece) variance of the matching estimator.

In sum, the main theoretical results available justify asymptotically the use of classical inference procedures based on the normal distribution, provided the standard errors are estimated appropriately. Computer programs implementing matching, which also compute matching estimators as well as other statistical procedures based on a matched sample, are available in commonly used statistical computing software such as MATLAB, R, and Stata.

MATRIX ALGEBRA

James Joseph Sylvester developed the modern concept of matrices in the 19th century. For him, a matrix was simply an array of numbers. He worked with systems of linear equations and so matrices provided a convenient way of working with the coefficients of these linear equations. In the process, matrix algebra was created to generalize number operations to a set of numbers called *matrices*. Nowadays, matrix algebra is used in all branches of mathematics and the sciences and constitutes the basis of most statistical procedures.

Matrices: Definition

A matrix is a set of numbers arranged in a table. For example, Toto, Marius, and Olivette are looking at their possessions, and they are counting how many balls, cars, coins, and novels they each possess. Toto has 2 balls, 5 cars, 10 coins, and 20 novels. Marius has 1, 2, 3, and 4, and Olivette has 6, 1, 3, and 10. These data can be displayed in a table in which each row represents a person and each column a possession:

Person	Balls	Cars	Coins	Novels
Toto	2	5	10	20
Marius	1	2	3	4
Olivette	6	1	3	10

We can also say that these data are described by the matrix denoted **A** equal to

$$\mathbf{A} = \begin{bmatrix} 2 & 5 & 10 & 20 \\ 1 & 2 & 3 & 4 \\ 6 & 1 & 3 & 10 \end{bmatrix}. \quad (1)$$

Matrices are denoted by boldface uppercase letters.

To identify a specific element of a matrix, we use its row and column numbers. For example, the cell defined by Row 3 and Column 1 contains the value 6: We write that $a_{3,1} = 6$. With this notation, elements of a matrix

are denoted with the same letter as the matrix but written in lowercase italic. The first subscript always gives the row number of the element (i.e., 3), and the second subscript always gives its column number (i.e., 1).

A generic element of a matrix is identified with indices such as i and j . So, $a_{i,j}$ is the element at the i th row and j th column of $\mathbf{A}$. The total number of rows and columns is denoted with the same letters as the indices but in uppercase letters. The matrix $\mathbf{A}$ has I rows (here $I = 3$) and J columns (here $J = 4$), and it is made of $I \times J$ elements $a_{i,j}$ (here $3 \times 4 = 12$). The term *dimensions* is often used to refer to the number of rows and columns, so $\mathbf{A}$ has dimensions I by J .

As a shortcut, a matrix can be represented by its generic element written in brackets. So, the matrix $\mathbf{A}$ with I rows and J columns is denoted

$$\mathbf{A} = [a_{i,j}] = \begin{bmatrix} a_{1,1} & a_{1,2} & \cdots & a_{1,j} & \cdots & a_{1,J} \\ a_{2,1} & a_{2,2} & \cdots & a_{2,j} & \cdots & a_{2,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{i,1} & a_{i,2} & \cdots & a_{i,j} & \cdots & a_{i,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{I,1} & a_{I,2} & \cdots & a_{I,j} & \cdots & a_{I,J} \end{bmatrix}. \quad (2)$$

For either convenience or clarity, the number of rows and columns can also be indicated as subscripts below the matrix name:

$$\mathbf{A} = \mathbf{A}_{I \times J} = [a_{i,j}]. \quad (3)$$

Vectors

A matrix with one column is called a *column vector* or simply a *vector*. Vectors are denoted with bold lowercase letters. For example, the first column of matrix $\mathbf{A}$ (of Equation 1) is a column vector that stores the number of balls of Toto, Marius, and Olivette. We can call it $\mathbf{b}$ (for balls), and so

$$\mathbf{b} = \begin{bmatrix} 2 \\ 1 \\ 6 \end{bmatrix}. \quad (4)$$

Vectors are the building blocks of matrices. For example, $\mathbf{A}$ (of Equation 1) is made of four column vectors, which represent the number of balls, cars, coins, and novels, respectively.

Norm of a Vector

We can associate to a vector a quantity, related to its variance and standard deviation, called the *norm* or

length. The norm of a vector is the square root of the sum of squares of the elements. It is denoted by putting the name of the vector between a set of double bars ($\|\cdot\|$). For example, for

$$\mathbf{x} = \begin{bmatrix} 2 \\ 1 \\ 2 \end{bmatrix} \quad (5)$$

we find

$$\|\mathbf{x}\| = \sqrt{2^2 + 1^2 + 2^2} = \sqrt{4 + 1 + 4} = \sqrt{9} = 3. \quad (6)$$

Normalization of a Vector

A vector is normalized when its norm is equal to 1. To normalize a vector, we divide each of its elements by its norm. For example, vector $\mathbf{x}$ from Equation 5 is transformed into the normalized vector $\bar{\mathbf{x}}$ as

$$\bar{\mathbf{x}} = \frac{\mathbf{x}}{\|\mathbf{x}\|} = \begin{bmatrix} \frac{2}{3} \\ \frac{1}{3} \\ \frac{2}{3} \end{bmatrix}. \quad (7)$$

Operations for Matrices

Transposition

If we exchange the roles of the rows and the columns of a matrix, we transpose it. This operation is called the *transposition*, and the new matrix is called a *transposed matrix*. The $\mathbf{A}$ matrix transposed is denoted $\mathbf{A}^T$. For example:

$$\text{if } \mathbf{A} = \mathbf{A}_{3 \times 4} = \begin{bmatrix} 2 & 5 & 10 & 20 \\ 1 & 2 & 3 & 4 \\ 6 & 1 & 3 & 10 \end{bmatrix},$$

then

$$\mathbf{A}^T = \mathbf{A}_{4 \times 3}^T = \begin{bmatrix} 2 & 1 & 6 \\ 5 & 2 & 1 \\ 10 & 3 & 3 \\ 20 & 4 & 10 \end{bmatrix} \quad (8)$$

Addition of Matrices

When two matrices have the same dimensions, we compute their sum by adding the corresponding elements. For example, with

$$\mathbf{A} = \begin{bmatrix} 2 & 5 & 10 & 20 \\ 1 & 2 & 3 & 4 \\ 6 & 1 & 3 & 10 \end{bmatrix} \text{ and} \quad (9)$$

$$\mathbf{B} = \begin{bmatrix} 3 & 4 & 5 & 6 \\ 2 & 4 & 6 & 8 \\ 1 & 2 & 3 & 5 \end{bmatrix},$$

we find that

$$\begin{aligned} \mathbf{A} + \mathbf{B} &= \begin{bmatrix} 2+3 & 5+4 & 10+5 & 20+6 \\ 1+2 & 2+4 & 3+6 & 4+8 \\ 6+1 & 1+2 & 3+3 & 10+5 \end{bmatrix} \\ &= \begin{bmatrix} 5 & 9 & 15 & 26 \\ 3 & 6 & 9 & 12 \\ 7 & 3 & 6 & 15 \end{bmatrix}. \end{aligned} \quad (10)$$

In general

$$\mathbf{A} + \mathbf{B} = \begin{bmatrix} a_{1,1} + b_{1,1} & a_{1,2} + b_{1,2} & \cdots & a_{1,i} + b_{1,i} & \cdots & a_{1,j} + b_{1,j} & \cdots & a_{1,J} + b_{1,J} \\ a_{2,1} + b_{2,1} & a_{2,2} + b_{2,2} & \cdots & a_{2,i} + b_{2,i} & \cdots & a_{2,j} + b_{2,j} & \cdots & a_{2,J} + b_{2,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{i,1} + b_{i,1} & a_{i,2} + b_{i,2} & \cdots & a_{i,i} + b_{i,i} & \cdots & a_{i,j} + b_{i,j} & \cdots & a_{i,J} + b_{i,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{I,1} + b_{I,1} & a_{I,2} + b_{I,2} & \cdots & a_{I,i} + b_{I,i} & \cdots & a_{I,j} + b_{I,j} & \cdots & a_{I,J} + b_{I,J} \end{bmatrix}. \quad (11)$$

Matrix addition behaves very much like usual addition. Specifically, matrix addition is commutative (i.e., $\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}$) and associative (i.e., $\mathbf{A} + [\mathbf{B} + \mathbf{C}] = [\mathbf{A} + \mathbf{B}] + \mathbf{C}$).

Multiplication of a Matrix by a Scalar

To differentiate matrices from the usual numbers, we call usual numbers scalar numbers or simply scalars. To multiply a matrix by a scalar, we multiply each element of the matrix by this scalar. For example,

$$\begin{aligned} 10 \times \mathbf{B} &= 10 \times \begin{bmatrix} 3 & 4 & 5 & 6 \\ 2 & 4 & 6 & 8 \\ 1 & 2 & 3 & 5 \end{bmatrix} \\ &= \begin{bmatrix} 30 & 40 & 50 & 60 \\ 20 & 40 & 60 & 80 \\ 10 & 20 & 30 & 50 \end{bmatrix}. \end{aligned} \quad (12)$$

Multiplication: Product or Products?

There are several ways of generalizing the concept of product or multiplication to matrices. We will look at the most frequently used of these matrix products. Each

of these products will behave like the product between scalars when the matrices have dimensions 1×1 .

Hadamard Product

When generalizing product to matrices, the first approach is to multiply the corresponding elements of the two matrices that we want to multiply. This is called the *Hadamard product*, denoted by $\odot$. The Hadamard product exists only for matrices with the same dimensions. Formally, it is defined as shown below:

$$\begin{aligned} \mathbf{A} \odot \mathbf{B} &= [a_{i,j} \times b_{i,j}] \\ &= \begin{bmatrix} a_{1,1} \times b_{1,1} & a_{1,2} \times b_{1,2} & \cdots & a_{1,i} \times b_{1,i} & \cdots & a_{1,j} \times b_{1,j} & \cdots & a_{1,J} \times b_{1,J} \\ a_{2,1} \times b_{2,1} & a_{2,2} \times b_{2,2} & \cdots & a_{2,i} \times b_{2,i} & \cdots & a_{2,j} \times b_{2,j} & \cdots & a_{2,J} \times b_{2,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{i,1} \times b_{i,1} & a_{i,2} \times b_{i,2} & \cdots & a_{i,i} \times b_{i,i} & \cdots & a_{i,j} \times b_{i,j} & \cdots & a_{i,J} \times b_{i,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{I,1} \times b_{I,1} & a_{I,2} \times b_{I,2} & \cdots & a_{I,i} \times b_{I,i} & \cdots & a_{I,j} \times b_{I,j} & \cdots & a_{I,J} \times b_{I,J} \end{bmatrix}. \end{aligned} \quad (13)$$

For example, with

$$\begin{aligned} \mathbf{A} &= \begin{bmatrix} 2 & 5 & 10 & 20 \\ 1 & 2 & 3 & 4 \\ 6 & 1 & 3 & 10 \end{bmatrix} \text{ and} \\ \mathbf{B} &= \begin{bmatrix} 3 & 4 & 5 & 6 \\ 2 & 4 & 6 & 8 \\ 1 & 2 & 3 & 5 \end{bmatrix}, \end{aligned} \quad (14)$$

we get

$$\begin{aligned} \mathbf{A} \odot \mathbf{B} &= \begin{bmatrix} 2 \times 3 & 5 \times 4 & 10 \times 5 & 20 \times 6 \\ 1 \times 2 & 2 \times 4 & 3 \times 6 & 4 \times 8 \\ 6 \times 1 & 1 \times 2 & 3 \times 3 & 10 \times 5 \end{bmatrix} \\ &= \begin{bmatrix} 6 & 20 & 50 & 120 \\ 2 & 8 & 18 & 32 \\ 6 & 2 & 9 & 50 \end{bmatrix}. \end{aligned} \quad (15)$$

Standard or Cayley Product

The Hadamard product is straightforward, but it is not the matrix product that is used most often. The product most often used is called the *standard* or *Cayley product*, or simply the *product* (i.e., when the name of the product is not specified, it is the standard product). The definition of the Cayley product comes from the original use of matrices to solve equations. Its definition looks surprising at first because it is defined only when the number of columns of the first matrix is equal to the number of rows of the second matrix. When two

matrices can be multiplied together, they are called *conformable*. This product will have the number of rows of the first matrix and the number of columns of the second matrix.

So, $\mathbf{A}$ with I rows and J columns can be multiplied by $\mathbf{B}$ with J rows and K columns to give $\mathbf{C}$ with I rows and K columns. A convenient way of checking that two matrices are conformable is to write the dimensions of the matrices as subscripts. For example,

$$\begin{matrix} \mathbf{A} \times \mathbf{B} = \mathbf{C}, \\ I \times J \quad J \times K \quad I \times K \end{matrix} \quad (16)$$

or even

$$I \mathbf{A}_J \mathbf{B}_K = \mathbf{C}_{I \times K}. \quad (17)$$

The element $c_{i,k}$ of matrix $\mathbf{C}$ is computed as

$$c_{i,k} = \sum_{j=1}^J a_{i,j} \times b_{j,k}. \quad (18)$$

So, $c_{i,k}$ is the sum of J terms, each term being the product of the corresponding element of the i th row of $\mathbf{A}$ with the k th column of $\mathbf{B}$.

For example, let

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 5 \end{bmatrix} \text{ and } \mathbf{B} = \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix}. \quad (19)$$

The product of these matrices is denoted $\mathbf{C} = \mathbf{A} \times \mathbf{B} = \mathbf{AB}$ (the $\times$ sign can be omitted when the context is clear). To compute $c_{2,1}$, we add three terms: (1) the product of the first element of the second row of $\mathbf{A}$ (i.e., 4) with the first element of the first column of $\mathbf{B}$ (i.e., 1), (2) the product of the second element of the second row of $\mathbf{A}$ (i.e., 5) with the second element of the first column of $\mathbf{B}$ (i.e., 3), and (3) the product of the third element of the second row of $\mathbf{A}$ (i.e., 5) with the third element of the first column of $\mathbf{B}$ (i.e., 5). Formally, the term $c_{2,1}$ is obtained as

$$\begin{aligned} c_{2,1} &= \sum_{j=1}^3 a_{2,j} \times b_{j,1} \\ &= (a_{2,1} \times b_{1,1}) + (a_{2,2} \times b_{2,1}) + (a_{2,3} \times b_{3,1}) \\ &= (4 \times 1) + (5 \times 3) + (6 \times 5) \\ &= 49. \end{aligned} \quad (20)$$

Matrix $\mathbf{C}$ is obtained as

$$\begin{aligned} c_{2,1} &= \sum_{j=1}^3 a_{2,j} \times b_{j,1} \\ &= (a_{2,1} \times b_{1,1}) + (a_{2,2} \times b_{2,1}) + (a_{2,3} \times b_{3,1}) \\ &= (4 \times 1) + (5 \times 3) + (6 \times 5) \\ &= 49. \end{aligned} \quad (20)$$

Properties of the Product

Like the product between scalars, the product between matrices is associative, and distributive relative to addition. Specifically, for any set of three conformable matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$:

$$(\mathbf{AB})\mathbf{C} = \mathbf{A}(\mathbf{BC}) = \mathbf{ABC} \text{ (associativity)} \quad (22)$$

$$\mathbf{A}(\mathbf{B} + \mathbf{C}) = \mathbf{AB} + \mathbf{AC} \text{ (distributivity)}. \quad (23)$$

The matrix products $\mathbf{AB}$ and $\mathbf{BA}$ do not always exist, but when they do, these products are not, in general, commutative. So:

$$\mathbf{AB} \neq \mathbf{BA}. \quad (24)$$

For example, with

$$\mathbf{A} = \begin{bmatrix} 2 & 1 \\ -2 & -1 \end{bmatrix} \text{ and } \mathbf{B} = \begin{bmatrix} 1 & -1 \\ -2 & 2 \end{bmatrix} \quad (25)$$

we get:

$$\mathbf{AB} = \begin{bmatrix} 2 & 1 \\ -2 & -1 \end{bmatrix} \begin{bmatrix} 1 & -1 \\ -2 & 2 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}. \quad (26)$$

But

$$\mathbf{BA} = \begin{bmatrix} 1 & -1 \\ -2 & 2 \end{bmatrix} \begin{bmatrix} 2 & 1 \\ -2 & -1 \end{bmatrix} = \begin{bmatrix} 4 & 2 \\ -8 & -4 \end{bmatrix}. \quad (27)$$

Incidentally, we can combine transposition and product and get the following equation:

$$(\mathbf{AB})^T = \mathbf{B}^T \mathbf{A}^T. \quad (28)$$

Exotic Product: Kronecker

Another product is the Kronecker product, also called the *direct*, *tensor*, or *Zehfuss product*. It is denoted $\otimes$ and is defined for all matrices. Specifically, with two matrices $\mathbf{A} = [a_{i,j}]$ (with dimensions I by J) and $\mathbf{B} = [b_{k,l}]$ (with dimensions K and L), the Kronecker product gives a matrix $\mathbf{C}$, with dimensions $(I \times K)$ by $(J \times L)$, defined as

$$\mathbf{A} \otimes \mathbf{B} = \begin{bmatrix} a_{1,1}\mathbf{B} & a_{1,2}\mathbf{B} & \cdots & a_{1,j}\mathbf{B} & \cdots & a_{1,J}\mathbf{B} \\ a_{2,1}\mathbf{B} & a_{2,2}\mathbf{B} & \cdots & a_{2,j}\mathbf{B} & \cdots & a_{2,J}\mathbf{B} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{i,1}\mathbf{B} & a_{i,2}\mathbf{B} & \cdots & a_{i,j}\mathbf{B} & \cdots & a_{i,J}\mathbf{B} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{I,1}\mathbf{B} & a_{I,2}\mathbf{B} & \cdots & a_{I,j}\mathbf{B} & \cdots & a_{I,J}\mathbf{B} \end{bmatrix}. \quad (29)$$

For example, with

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \end{bmatrix} \text{ and } \mathbf{B} = \begin{bmatrix} 6 & 7 \\ 8 & 9 \end{bmatrix} \quad (30)$$

we get

$$\begin{aligned} \mathbf{A} \otimes \mathbf{B} &= \begin{bmatrix} 1 \times 6 & 1 \times 7 & 2 \times 6 & 2 \times 7 & 3 \times 6 & 3 \times 7 \\ 1 \times 8 & 1 \times 9 & 2 \times 8 & 2 \times 9 & 3 \times 8 & 3 \times 9 \end{bmatrix} \\ &= \begin{bmatrix} 6 & 7 & 12 & 14 & 18 & 21 \\ 8 & 9 & 16 & 18 & 24 & 27 \end{bmatrix}. \end{aligned} \quad (31)$$

The Kronecker product is used to write design matrices. It is an essential tool for the derivation of expected values and sampling distributions.

Special Matrices

Certain special matrices have specific names.

Square and Rectangular Matrices

A matrix with the same number of rows and columns is a *square matrix*. By contrast, a matrix with different numbers of rows and columns is a *rectangular matrix*. So

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 5 \\ 7 & 8 & 0 \end{bmatrix} \quad (32)$$

is a square matrix, but

$$\mathbf{B} = \begin{bmatrix} 1 & 2 \\ 4 & 5 \\ 7 & 8 \end{bmatrix} \quad (33)$$

is a rectangular matrix.

Symmetric Matrix

A square matrix $\mathbf{A}$ with $a_{i,j} = a_{j,i}$ is symmetric. So

$$\mathbf{A} = \begin{bmatrix} 10 & 2 & 3 \\ 2 & 20 & 5 \\ 3 & 5 & 30 \end{bmatrix} \quad (34)$$

is symmetric, but

$$\mathbf{A} = \begin{bmatrix} 12 & 2 & 3 \\ 4 & 20 & 5 \\ 7 & 8 & 30 \end{bmatrix} \quad (35)$$

is not.

Note that for a symmetric matrix,

$$\mathbf{A} = \mathbf{A}^T. \quad (36)$$

A common mistake is to assume that the standard product of two symmetric matrices is commutative. But this is not true, as shown by the following example. With

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 1 & 4 \\ 3 & 4 & 1 \end{bmatrix} \text{ and } \mathbf{B} = \begin{bmatrix} 1 & 1 & 2 \\ 1 & 1 & 3 \\ 2 & 3 & 1 \end{bmatrix} \quad (37)$$

we get

$$\mathbf{AB} = \begin{bmatrix} 9 & 12 & 11 \\ 11 & 15 & 11 \\ 9 & 10 & 19 \end{bmatrix}, \text{ but } \mathbf{BA} = \begin{bmatrix} 9 & 11 & 9 \\ 12 & 15 & 10 \\ 11 & 11 & 19 \end{bmatrix}. \quad (38)$$

Note, however, that combining Equations 35 and 43 gives for symmetric matrices $\mathbf{A}$ and $\mathbf{B}$ the following equation:

$$\mathbf{AB} = (\mathbf{BA})^T. \quad (39)$$

Diagonal Matrix

A square matrix is diagonal when all its elements are zero except the elements on the diagonal. Formally, a matrix is diagonal if $a_{i,j} = 0$ when $i \neq j$. Thus,

$$\mathbf{A} = \begin{bmatrix} 10 & 0 & 0 \\ 0 & 20 & 0 \\ 0 & 0 & 30 \end{bmatrix} \text{ is diagonal.} \quad (40)$$

Because only the diagonal elements matter for a diagonal matrix, we can specify only these diagonal elements. This is done with the following notation:

$$\begin{aligned} \mathbf{A} &= \text{diag} \{ [a_{1,1}, \dots, a_{i,i}, \dots, a_{I,I}] \} \\ &= \text{diag} \{ [a_{i,i}] \}. \end{aligned} \quad (41)$$

For example, the previous matrix can be rewritten as:

$$\mathbf{A} = \begin{bmatrix} 10 & 0 & 0 \\ 0 & 20 & 0 \\ 0 & 0 & 30 \end{bmatrix} = \text{diag} \{ [10, 20, 30] \}. \quad (42)$$

The operator diag can also be used to isolate the diagonal of any square matrix. For example, with

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{bmatrix} \quad (43)$$

we get

$$\text{diag} \{ \mathbf{A} \} = \text{diag} \left\{ \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{bmatrix} \right\} = \begin{bmatrix} 1 \\ 5 \\ 9 \end{bmatrix}. \quad (44)$$

Note, incidentally, that

$$\text{diag}\{\text{diag}\{\mathbf{A}\}\} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 5 & 0 \\ 0 & 0 & 9 \end{bmatrix}. \quad (45)$$

Multiplication by a Diagonal Matrix

Diagonal matrices are often used to multiply by a scalar all the elements of a given row or column. Specifically, when we premultiply a matrix by a diagonal matrix, the elements of the row of the second matrix are multiplied by the corresponding diagonal element. Likewise, when we postmultiply a matrix by a diagonal matrix, the elements of the column of the first matrix are multiplied by the corresponding diagonal element. For example, with:

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} 2 & 0 \\ 0 & 5 \end{bmatrix} \quad \mathbf{C} = \begin{bmatrix} 2 & 0 & 0 \\ 0 & 4 & 0 \\ 0 & 0 & 6 \end{bmatrix}, \quad (46)$$

we get

$$\mathbf{BA} = \begin{bmatrix} 2 & 0 \\ 0 & 5 \end{bmatrix} \times \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} = \begin{bmatrix} 2 & 4 & 6 \\ 20 & 25 & 30 \end{bmatrix} \quad (47)$$

and

$$\mathbf{AC} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} \times \begin{bmatrix} 2 & 0 & 0 \\ 0 & 4 & 0 \\ 0 & 0 & 6 \end{bmatrix} = \begin{bmatrix} 2 & 8 & 18 \\ 8 & 20 & 36 \end{bmatrix} \quad (48)$$

and also

$$\mathbf{BAC} = \begin{bmatrix} 2 & 0 \\ 0 & 5 \end{bmatrix} \times \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} \times \begin{bmatrix} 2 & 0 & 0 \\ 0 & 4 & 0 \\ 0 & 0 & 6 \end{bmatrix} = \begin{bmatrix} 4 & 16 & 36 \\ 40 & 100 & 180 \end{bmatrix}. \quad (49)$$

Identity Matrix

A diagonal matrix whose diagonal elements are all equal to 1 is called an *identity matrix* and is denoted $\mathbf{I}$. If we need to specify its dimensions, we use subscripts such as, for example:

$$\mathbf{I}_{3 \times 3} = \mathbf{I} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \text{ (this is a } 3 \times 3 \text{ identity matrix).} \quad (50)$$

The identity matrix is the neutral element for the standard product. So

$$\mathbf{I} \times \mathbf{A} = \mathbf{A} \times \mathbf{I} = \mathbf{A} \quad (51)$$

for any matrix $\mathbf{A}$ conformable with $\mathbf{I}$. For example:

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \times \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 5 \\ 7 & 8 & 0 \end{bmatrix} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 5 \\ 7 & 8 & 0 \end{bmatrix} \quad (52)$$

$$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 5 \\ 7 & 8 & 0 \end{bmatrix} \times \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 5 \\ 7 & 8 & 0 \end{bmatrix}.$$

Matrix Full of Ones

A matrix whose elements are all equal to 1 is denoted by $\mathbf{1}$ or, when we need to specify its dimensions by writing, for example: $\mathbf{1}_{I \times J}$.

These matrices are neutral elements for the Hadamard product. So

$$\mathbf{A} \odot \mathbf{1}_{2 \times 3} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} \odot \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \quad (53)$$

$$= \begin{bmatrix} 1 \times 1 & 2 \times 1 & 3 \times 1 \\ 4 \times 1 & 5 \times 1 & 6 \times 1 \end{bmatrix} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix}. \quad (54)$$

The $\mathbf{1}$ matrices or vectors can also be used to compute sums of rows or columns:

$$\begin{bmatrix} 1 & 2 & 3 \end{bmatrix} \times \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} = (1 \times 1) + (2 \times 1) + (3 \times 1) \quad (55)$$

$$= 1 + 2 + 3 = 6,$$

or also

$$\begin{bmatrix} 1 & 1 \end{bmatrix} \times \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} = \begin{bmatrix} 5 & 7 & 9 \end{bmatrix}. \quad (56)$$

Matrix Full of Zeros

A matrix whose elements are all equal to 0 is the null or zero matrix. It is denoted by $\mathbf{0}$ or, when we need to specify its dimensions, by $\mathbf{0}_{I \times J}$. Null matrices are neutral elements for addition:

$$\begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix} + \mathbf{0}_{2 \times 2} = \begin{bmatrix} 1+0 & 2+0 \\ 3+0 & 4+0 \end{bmatrix} = \begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix}. \quad (57)$$

Null matrices are also null elements for the Hadamard product:

$$\begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix} \odot \mathbf{0}_{2 \times 2} = \begin{bmatrix} 1 \times 0 & 2 \times 0 \\ 3 \times 0 & 4 \times 0 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} = \mathbf{0}_{2 \times 2} \quad (58)$$

as well as for the standard product:

$$\begin{aligned} \begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix} \times \mathbf{0}_{2 \times 2} &= \begin{bmatrix} 1 \times 0 + 2 \times 0 & 1 \times 0 + 2 \times 0 \\ 3 \times 0 + 4 \times 0 & 3 \times 0 + 4 \times 0 \end{bmatrix} \\ &= \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}_{2 \times 2} = \mathbf{0}_{2 \times 2}. \end{aligned} \quad (59)$$

Triangular Matrix

A matrix is lower triangular when $a_{ij} = 0$ for $i < j$. A matrix is upper triangular when $a_{ij} = 0$ for $i > j$. For example,

$$\mathbf{A} = \begin{bmatrix} 10 & 0 & 0 \\ 2 & 20 & 0 \\ 3 & 5 & 30 \end{bmatrix} \text{ is lower triangular} \quad (60)$$

and

$$\mathbf{B} = \begin{bmatrix} 12 & 2 & 3 \\ 0 & 20 & 5 \\ 0 & 0 & 30 \end{bmatrix} \text{ is upper triangular.} \quad (61)$$

Cross-Product Matrix

A cross-product matrix is obtained by multiplication of a matrix by its transpose. Therefore, a cross-product matrix is square and symmetric. For example, the matrix:

$$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 2 & 4 \\ 3 & 4 \end{bmatrix} \quad (62)$$

premultiplied by its transpose

$$\mathbf{A}^T = \begin{bmatrix} 1 & 2 & 3 \\ 1 & 4 & 4 \end{bmatrix} \quad (63)$$

gives the following cross-product matrix:

$$\begin{aligned} \mathbf{A}^T \mathbf{A} &= \begin{bmatrix} 1 \times 1 + 2 \times 2 + 3 \times 3 & 1 \times 1 + 2 \times 4 + 3 \times 4 \\ 1 \times 1 + 4 \times 2 + 4 \times 3 & 1 \times 1 + 4 \times 4 + 4 \times 4 \end{bmatrix} \\ &= \begin{bmatrix} 14 & 21 \\ 14 & 33 \end{bmatrix}. \end{aligned} \quad (64)$$

A Particular Case of Cross-Product Matrix: Variance–Covariance Matrix

A particular case of cross-product matrices is correlation or covariance matrices. A variance–covariance matrix is obtained from a data matrix by three steps: (1) subtract the mean of each column from each element of this column (this is centering), (2) compute the cross-product matrix from the centered matrix, and (3)

divide each element of the cross-product matrix by the number of rows of the data matrix. For example, if we take the $I = 3$ by $J = 2$ matrix $\mathbf{A}$,

$$\mathbf{A} = \begin{bmatrix} 2 & 1 \\ 5 & 10 \\ 8 & 10 \end{bmatrix}, \quad (65)$$

we obtain the means of each column as

$$\begin{aligned} \mathbf{m} &= \frac{1}{I} \times \mathbf{1}_{1 \times I} \times \mathbf{A}_{I \times J} \\ &= \frac{1}{3} \times [1 \ 1 \ 1] \times \begin{bmatrix} 2 & 1 \\ 5 & 10 \\ 8 & 10 \end{bmatrix} = [5 \ 7]. \end{aligned} \quad (66)$$

To center the matrix, we subtract the mean of each column from all its elements. This centered matrix gives the deviations of each element from the mean of its column. Centering is performed as

$$\mathbf{D} = \mathbf{A} - \mathbf{1}_{J \times 1} \times \mathbf{m} = \begin{bmatrix} 2 & 1 \\ 5 & 10 \\ 8 & 10 \end{bmatrix} - \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} \times [5 \ 7] \quad (67)$$

$$= \begin{bmatrix} 2 & 1 \\ 5 & 10 \\ 8 & 10 \end{bmatrix} - \begin{bmatrix} 5 & 7 \\ 5 & 7 \\ 5 & 7 \end{bmatrix} = \begin{bmatrix} -3 & -6 \\ 0 & 3 \\ 3 & 3 \end{bmatrix}. \quad (68)$$

We denote by $\mathbf{S}$ the variance–covariance matrix derived from $\mathbf{A}$. It is computed as

$$\begin{aligned} \mathbf{S} &= \frac{1}{I} \mathbf{D}^T \mathbf{D} = \frac{1}{3} \begin{bmatrix} -3 & 0 & 3 \\ -6 & 3 & 3 \end{bmatrix} \times \begin{bmatrix} -3 & -6 \\ 0 & 3 \\ 3 & 3 \end{bmatrix} \\ &= \frac{1}{3} \times \begin{bmatrix} 18 & 27 \\ 27 & 54 \end{bmatrix} = \begin{bmatrix} 6 & 9 \\ 9 & 18 \end{bmatrix}. \end{aligned} \quad (69)$$

(Variances are on the diagonal; covariances are off-diagonal.)

The Inverse of a Square Matrix

An operation similar to division exists, but only for (some) square matrices. This operation uses the notion of inverse operation and defines the inverse of a matrix. The inverse is defined by analogy with the scalar number case, for which division actually corresponds to multiplication by the inverse, namely,

$$\frac{a}{b} = a \times b^{-1} \text{ with } b \times b^{-1} = 1. \quad (70)$$

The inverse of a square matrix $\mathbf{A}$ is denoted $\mathbf{A}^{-1}$. It has the following property:

$$\mathbf{A} \times \mathbf{A}^{-1} = \mathbf{A}^{-1} \times \mathbf{A} = \mathbf{I}. \quad (71)$$

The definition of the inverse of a matrix is simple, but its computation is complicated and is best left to computers.

As an example, for

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad (72)$$

the inverse is:

$$\mathbf{A}^{-1} = \begin{bmatrix} 1 & -2 & -1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (73)$$

All square matrices do not necessarily have an inverse. The inverse of a matrix does not exist if the rows (and the columns) of this matrix are linearly dependent. For example, this matrix

$$\mathbf{A} = \begin{bmatrix} 3 & 4 & 2 \\ 1 & 0 & 2 \\ 2 & 1 & 3 \end{bmatrix} \quad (74)$$

does not have an inverse because the second column is a linear combination of the two other columns:

$$\begin{bmatrix} 4 \\ 0 \\ 1 \end{bmatrix} = 2 \times \begin{bmatrix} 3 \\ 1 \\ 2 \end{bmatrix} - \begin{bmatrix} 2 \\ 2 \\ 3 \end{bmatrix} = \begin{bmatrix} 6 \\ 2 \\ 4 \end{bmatrix} - \begin{bmatrix} 2 \\ 2 \\ 3 \end{bmatrix}. \quad (75)$$

A matrix without an inverse is called *singular*. When $\mathbf{A}^{-1}$ exists, it is unique.

Inverse matrices are used for solving linear equations and least square problems in, for example, multiple regression analysis, analysis of variance, and, of course, multivariate analysis.

Inverse of a Diagonal Matrix

The inverse of a diagonal matrix is easy to compute: The inverse of

$$\mathbf{A} = \text{diag}\{a_{i,i}\} \quad (76)$$

is the diagonal matrix

$$\mathbf{A}^{-1} = \text{diag}\{a_{i,i}^{-1}\} = \text{diag}\{1/a_{i,i}\}. \quad (77)$$

For example,

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & .5 & 0 \\ 0 & 0 & 4 \end{bmatrix} \text{ and } \begin{bmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & .25 \end{bmatrix} \quad (78)$$

are inverse of each other.

The Big Tool: The Eigen Decomposition

So far, matrix operations are very similar to operations with numbers. The next notion is specific to matrices. This is the idea of decomposing a matrix into simpler matrices. A lot of the power of matrices follows from this. A first decomposition is called the *Eigen decomposition*, and it applies only to square matrices. The generalization of the Eigen decomposition to rectangular matrices is called the *singular value* decomposition.

Eigenvectors and *eigenvalues* are numbers and vectors associated with square matrices. Together they constitute the Eigen decomposition. Even though the Eigen decomposition does not exist for all square matrices, it has a particularly simple expression for a class of matrices often used in multivariate analysis such as correlation, covariance, or cross-product matrices. The Eigen decomposition of these matrices is important in statistics because it is used to find the maximum (or minimum) of functions involving these matrices. For example, principal components analysis is obtained from the Eigen decomposition of a covariance or correlation matrix and gives the least square estimate of the original data matrix.

Notations and Definition

An *eigenvector* of matrix $\mathbf{A}$ is a vector $\mathbf{u}$ that satisfies the following equation:

$$\mathbf{A}\mathbf{u} = \lambda\mathbf{u}, \quad (79)$$

where λ is a scalar called the *eigenvalue* associated with the eigenvector. When rewritten, Equation 79 becomes

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{u} = 0. \quad (80)$$

Therefore, $\mathbf{u}$ is eigenvector of $\mathbf{A}$ if the multiplication of $\mathbf{u}$ by $\mathbf{A}$ changes the length of $\mathbf{u}$ but not its orientation. For example,

$$\mathbf{A} = \begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \quad (81)$$

has for eigenvectors

$$\mathbf{u}_1 = \begin{bmatrix} 3 \\ 2 \end{bmatrix} \text{ with eigenvalue } \lambda_1 = 4 \quad (82)$$

and

$$\mathbf{u}_2 = \begin{bmatrix} -1 \\ 1 \end{bmatrix} \text{ with eigenvalue } \lambda_2 = -1. \quad (83)$$

When $\mathbf{u}_1$ and $\mathbf{u}_2$ are multiplied by $\mathbf{A}$, only their length changes. That is,

$$\mathbf{A}\mathbf{u}_1 = \lambda_1\mathbf{u}_1 = \begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} 3 \\ 2 \end{bmatrix} = \begin{bmatrix} 12 \\ 8 \end{bmatrix} = 4 \begin{bmatrix} 3 \\ 2 \end{bmatrix} \quad (84)$$

and

$$\mathbf{A}\mathbf{u}_2 = \lambda_2\mathbf{u}_2 = \begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} -1 \\ 1 \end{bmatrix} = \begin{bmatrix} 1 \\ -1 \end{bmatrix} = -1 \begin{bmatrix} -1 \\ 1 \end{bmatrix}. \quad (85)$$

This is illustrated in Figure 1.

For convenience, eigenvectors are generally normalized such that

$$\mathbf{u}^T \mathbf{u} = 1. \quad (86)$$

For the previous example, normalizing the eigenvectors gives

$$\mathbf{u}_1 = \begin{bmatrix} .8321 \\ .5547 \end{bmatrix} \text{ and } \mathbf{u}_2 = \begin{bmatrix} -.7071 \\ .7071 \end{bmatrix}. \quad (87)$$

We can check that

$$\begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} .8321 \\ .5547 \end{bmatrix} = \begin{bmatrix} 3.3284 \\ 2.2188 \end{bmatrix} = 4 \begin{bmatrix} .8321 \\ .5547 \end{bmatrix} \quad (88)$$

and

$$\begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} -.7071 \\ .7071 \end{bmatrix} = \begin{bmatrix} .7071 \\ -.7071 \end{bmatrix} = -1 \begin{bmatrix} -.7071 \\ .7071 \end{bmatrix}. \quad (89)$$

Eigenvector and Eigenvalue Matrices

Traditionally, we store the eigenvectors of matrix $\mathbf{A}$ as the columns of a matrix denoted $\mathbf{U}$. Eigenvalues are stored in a diagonal matrix (denoted Λ , which is the

Figure 1 Two Eigenvectors of a Matrix

upper case Greek letter lambda). Therefore, Equation 79 becomes

$$\mathbf{A}\mathbf{U} = \mathbf{U}\Lambda. \quad (90)$$

For example, with $\mathbf{A}$ (from Equation 81), we have

$$\begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \times \begin{bmatrix} 3 & -1 \\ 2 & 1 \end{bmatrix} = \begin{bmatrix} 3 & -1 \\ 2 & 1 \end{bmatrix} \times \begin{bmatrix} 4 & 0 \\ 0 & -1 \end{bmatrix}. \quad (91)$$

Reconstitution of a Matrix

The Eigen decomposition can also be used to build back a matrix from its eigenvectors and eigenvalues. This is shown by rewriting Equation 90 as

$$\mathbf{A} = \mathbf{U}\Lambda\mathbf{U}^{-1}. \quad (92)$$

For example, because

$$\mathbf{U}^{-1} = \begin{bmatrix} .2 & .2 \\ -.4 & .6 \end{bmatrix},$$

we obtain

$$\mathbf{A} = \mathbf{U}\Lambda\mathbf{U}^{-1} = \begin{bmatrix} 3 & -1 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} 4 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} .2 & .2 \\ -.4 & .6 \end{bmatrix} = \begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix}. \quad (93)$$

Digression: An Infinity of Eigenvectors for One Eigenvalue

It is only through a slight abuse of language that we talk about *the* eigenvector associated with *one* eigenvalue. Any scalar multiple of an eigenvector is an eigenvector, so for each eigenvalue, there is an infinite number of eigenvectors, all proportional to each other. For example,

$$\begin{bmatrix} 1 \\ -1 \end{bmatrix} \quad (94)$$

is an eigenvector of $\mathbf{A}$:

$$\begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} 1 \\ -1 \end{bmatrix} = \begin{bmatrix} -1 \\ 0 \end{bmatrix} = -1 \begin{bmatrix} 1 \\ -1 \end{bmatrix}. \quad (95)$$

Therefore,

$$2 \times \begin{bmatrix} 1 \\ -1 \end{bmatrix} = \begin{bmatrix} 2 \\ -2 \end{bmatrix} \quad (96)$$

is also an eigenvector of $\mathbf{A}$:

$$\begin{bmatrix} 2 & 3 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} 2 \\ -2 \end{bmatrix} = \begin{bmatrix} -2 \\ 2 \end{bmatrix} = -1 \times 2 \begin{bmatrix} 1 \\ -1 \end{bmatrix}. \quad (97)$$

Positive (semi)definite Matrices

Some matrices, such as $\begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$, do not have eigenvalues. Fortunately, the matrices used often in statistics belong to a category called *positive semidefinite*. The Eigen decomposition of these matrices always exists and has a particularly convenient form. A matrix is positive semidefinite when it can be obtained as the product of a matrix by its transpose. This implies that a positive semidefinite matrix is always symmetric. So, formally, the matrix $\mathbf{A}$ is positive semidefinite if it can be obtained as

$$\mathbf{A} = \mathbf{X}\mathbf{X}^T \quad (98)$$

for a certain matrix $\mathbf{X}$. Positive semidefinite matrices include correlation, covariance, and cross-product matrices.

The eigenvalues of a positive semidefinite matrix are always positive or null, and the eigenvectors of a positive semidefinite matrix are composed of real values and are pairwise orthogonal when their eigenvalues are different. This implies the following equality:

$$\mathbf{U}^{-1} = \mathbf{U}^T. \quad (99)$$

We can, therefore, express the positive semidefinite matrix $\mathbf{A}$ as

$$\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^T \quad (100)$$

where $\mathbf{U}$ (with $\mathbf{U}^T\mathbf{U} = \mathbf{I}$) are the normalized eigenvectors. For example

$$\mathbf{A} = \begin{bmatrix} 3 & 1 \\ 1 & 3 \end{bmatrix} \quad (101)$$

can be decomposed as

$$\begin{aligned} \mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U} &= \begin{bmatrix} \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} \end{bmatrix} \begin{bmatrix} 4 & 0 \\ 0 & 2 \end{bmatrix} \begin{bmatrix} \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} \end{bmatrix} \\ &= \begin{bmatrix} 3 & 1 \\ 1 & 3 \end{bmatrix}, \end{aligned} \quad (102)$$

with

$$\begin{bmatrix} \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} \end{bmatrix} \times \begin{bmatrix} \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} \\ \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}. \quad (103)$$

Diagonalization

When a matrix is positive semidefinite, we can rewrite Equation 100 as

$$\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^T \Leftrightarrow \mathbf{\Lambda} = \mathbf{U}^T\mathbf{A}\mathbf{U}. \quad (104)$$

This shows that we can transform $\mathbf{A}$ into a *diagonal* matrix, and so the Eigen decomposition of a positive semidefinite matrix is often called its *diagonalization*.

Another Definition for Positive Semidefinite Matrices

A matrix $\mathbf{A}$ is positive semidefinite if for any non-zero vector $\mathbf{x}$, we have

$$\mathbf{x}^T\mathbf{A}\mathbf{x} \geq 0 \quad \forall \mathbf{x}. \quad (105)$$

When *all* the eigenvalues of a matrix are positive, the matrix is *positive definite*. In that case, Equation 105 becomes

$$\mathbf{x}^T\mathbf{A}\mathbf{x} > 0 \quad \forall \mathbf{x}. \quad (106)$$

Trace, Determinant, and Rank

The eigenvalues of a matrix are closely related to three important numbers associated with a square matrix: the *trace*, the *determinant*, and the *rank*.

Trace

The trace of $\mathbf{A}$, denoted $\text{trace}\{\mathbf{A}\}$, is the sum of its diagonal elements. For example, with

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{bmatrix} \quad (107)$$

we obtain

$$\text{trace}\{\mathbf{A}\} = 1 + 5 + 9 = 15. \quad (108)$$

The trace of a matrix is also equal to the sum of its eigenvalues:

$$\text{trace}\{\mathbf{A}\} = \sum_{\ell} \lambda_{\ell} = \text{trace}\{\mathbf{\Lambda}\} \quad (109)$$

with $\mathbf{\Lambda}$ being the matrix of the eigenvalues of $\mathbf{A}$. For the previous example, we have

$$\mathbf{\Lambda} = \text{diag}\{16.1168, -1.1168, 0\}. \quad (110)$$

We can verify that

$$\text{trace}\{\mathbf{A}\} = \sum_{\ell} \lambda_{\ell} = 16.1168 + (-1.1168) = 15. \quad (111)$$

Determinant

The *determinant* is important for finding the solution of systems of linear equations (i.e., the determinant *determines* the existence of a solution). The determinant of a matrix is equal to the product of its eigenvalues. If $\det\{\mathbf{A}\}$ is the determinant of $\mathbf{A}$,

$$\det\{\mathbf{A}\} = \prod_{\ell} \lambda_{\ell} \text{ with } \lambda_{\ell} \text{ being the } \ell \text{th eigenvalue of } \mathbf{A}. \quad (112)$$

For example, the determinant of $\mathbf{A}$ from Equation 107 is equal to

$$\det\{\mathbf{A}\} = 16.1168 \times -1.1168 \times 0 = 0. \quad (113)$$

Rank

Finally, the *rank* of a matrix is the number of non-zero eigenvalues of the matrix. For our example,

$$\text{rank}\{\mathbf{A}\} = 2. \quad (114)$$

The rank of a matrix gives the dimensionality of the Euclidean space that can be used to represent this matrix. Matrices whose rank is equal to their dimensions are full rank, and they are invertible. When the rank of a matrix is smaller than its dimensions, the matrix is not invertible and is called rank-deficient, singular, or multicollinear. For example, matrix $\mathbf{A}$ from Equation 107 is a 3×3 square matrix, its rank is equal to 2, and therefore it is rank-deficient and does not have an inverse.

Statistical Properties of the Eigen Decomposition

The Eigen decomposition is essential in optimization. For example, principal components analysis is a technique used to analyze an $I \times J$ matrix $\mathbf{X}$ in which the rows are observations and the columns are variables. Principal components analysis finds orthogonal row *factor scores* that “explain” as much of the variance of $\mathbf{X}$ as possible. They are obtained as

$$\mathbf{F} = \mathbf{X}\mathbf{Q} \quad (115)$$

where $\mathbf{F}$ is the matrix of factor scores and $\mathbf{Q}$ is the matrix of loadings of the variables. These loadings give the coefficients of the linear combination used to compute the factor scores from the variables. In addition to Equation 115, we impose the constraints that

$$\mathbf{F}^T \mathbf{F} = \mathbf{Q}^T \mathbf{X}^T \mathbf{X} \mathbf{Q} \quad (116)$$

is a diagonal matrix (i.e., $\mathbf{F}$ is an orthogonal matrix) and that

$$\mathbf{Q}^T \mathbf{Q} = \mathbf{I} \quad (117)$$

(i.e., $\mathbf{Q}$ is an orthonormal matrix). The solution is obtained by using Lagrange multipliers in which the constraint from Equation 117 is expressed as the multiplication with a diagonal matrix of Lagrange multipliers denoted Λ ; in order to give the following expression:

$$\Lambda(\mathbf{Q}^T \mathbf{Q} - \mathbf{I}). \quad (118)$$

This amounts to defining the following equation:

$$\mathbf{L} = \mathbf{F}^T \mathbf{F} - \Lambda(\mathbf{Q}^T \mathbf{Q} - \mathbf{I}). \quad (119)$$

The values of $\mathbf{Q}$ that give the maximum values of $\mathcal{L}$ are found by first computing the derivative of $\mathcal{L}$ relative to $\mathbf{Q}$,

$$\frac{\partial \mathcal{L}}{\partial \mathbf{Q}} = 2\mathbf{X}^T \mathbf{X} \mathbf{Q} - 2\Lambda \mathbf{Q}, \quad (120)$$

and setting this derivative to zero:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{Q}} = \mathbf{X}^T \mathbf{X} \mathbf{Q} - \Lambda \mathbf{Q} = 0 \in \mathbf{X}^T \mathbf{X} \mathbf{Q} = \Lambda \mathbf{Q}. \quad (121)$$

Because Λ is diagonal, this is an Eigen decomposition problem, Λ is the matrix of eigenvalues of the positive semidefinite matrix $\mathbf{X}^T \mathbf{X}$ ordered from the largest to the smallest, and $\mathbf{Q}$ is the matrix of eigenvectors of $\mathbf{X}^T \mathbf{X}$. Finally, the factor matrix is

$$\mathbf{F} = \mathbf{X}\mathbf{Q}. \quad (123)$$

The variance of the factor scores is equal to the eigenvalues:

$$\mathbf{F}^T \mathbf{F} = \mathbf{Q}^T \mathbf{X}^T \mathbf{X} \mathbf{Q} = \mathbf{Q}^T \mathbf{Q} \Lambda \mathbf{Q}^T \mathbf{Q} = \Lambda. \quad (123)$$

Because the sum of the eigenvalues is equal to the trace of $\mathbf{X}^T \mathbf{X}$, the set of the first factor scores “extracts” as much of the variance of the original data as possible, the second set of factor scores extracts as much of the variance left unexplained by the first factor as possible, and so on for the remaining factors. The diagonal elements of the matrix $\Lambda^{\frac{1}{2}}$, which are the standard deviations of the factor scores, are called the *singular values* of $\mathbf{X}$.

A Tool for Rectangular Matrices: The Singular Value Decomposition

The singular value decomposition (SVD) generalizes the Eigen decomposition to rectangular matrices. The Eigen decomposition decomposes a matrix into *two* simple matrices, and the SVD decomposes a rectangular matrix into *three* simple matrices: two orthogonal matrices and one diagonal matrix. The SVD uses the

Eigen decomposition of a positive semidefinite matrix to derive a similar decomposition for rectangular matrices.

Definitions and Notations

The SVD decomposes matrix $\mathbf{A}$ as

$$\mathbf{A} = \mathbf{P}\Delta\mathbf{Q}^T, \quad (124)$$

where $\mathbf{P}$ is the matrix storing the (normalized) eigenvectors of the matrix $\mathbf{A}\mathbf{A}^T$ (i.e., $\mathbf{P}^T\mathbf{P} = \mathbf{I}$). The columns of $\mathbf{P}$ are called the *left singular vectors* of $\mathbf{A}$. Matrix $\mathbf{Q}$ stores the (normalized) eigenvectors of the matrix $\mathbf{A}^T\mathbf{A}$ (i.e., $\mathbf{Q}^T\mathbf{Q} = \mathbf{I}$). The columns of $\mathbf{Q}$ are called the *right singular vectors* of $\mathbf{A}$. The matrix Δ is the diagonal matrix of the *singular values*, $\Delta = \Lambda^{\frac{1}{2}}$, with Λ being the diagonal matrix of the eigenvalues of $\mathbf{A}\mathbf{A}^T$ and $\mathbf{A}^T\mathbf{A}$.

The SVD is derived from the Eigen decomposition of a positive semidefinite matrix. This is shown by considering the Eigen decomposition of the two positive semidefinite matrices obtained from $\mathbf{A}$, namely, $\mathbf{A}\mathbf{A}^T$ and $\mathbf{A}^T\mathbf{A}$. If we express these matrices in terms of the SVD of $\mathbf{A}$, we find

$$\mathbf{A}\mathbf{A}^T = \mathbf{P}\Delta\mathbf{Q}^T\mathbf{Q}\Delta\mathbf{P}^T = \mathbf{P}\Delta^2\mathbf{P}^T = \mathbf{P}\Lambda\mathbf{P}^T \quad (125)$$

and

$$\mathbf{A}^T\mathbf{A} = \mathbf{Q}\Delta\mathbf{P}^T\mathbf{P}\Delta\mathbf{Q}^T = \mathbf{Q}\Delta^2\mathbf{Q}^T = \mathbf{Q}\Lambda\mathbf{Q}^T. \quad (126)$$

This equation shows that Δ is the square root of Λ , that $\mathbf{P}$ is the matrix of the eigenvectors of $\mathbf{A}\mathbf{A}^T$, and that $\mathbf{Q}$ is the matrix of the eigenvectors of $\mathbf{A}^T\mathbf{A}$. For example, the matrix

$$\mathbf{A} = \begin{bmatrix} 1.1547 & -1.1547 \\ -1.0774 & 0.0774 \\ -0.0774 & 1.0774 \end{bmatrix} \quad (127)$$

can be expressed as

$$\begin{aligned} \mathbf{A} = \mathbf{P}\mathbf{Q}^T &= \begin{bmatrix} 0.8165 & 0 \\ -0.4082 & -0.7071 \\ -0.4082 & -0.7071 \end{bmatrix} \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & -0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 1.1547 & -1.1547 \\ -0.0774 & 0.0774 \\ -0.0774 & 1.0774 \end{bmatrix}. \end{aligned} \quad (128)$$

We can check that

$$\begin{aligned} \mathbf{A}\mathbf{A}^T &= \begin{bmatrix} 0.8165 & 0 \\ -0.4082 & -0.7071 \\ -0.4082 & -0.7071 \end{bmatrix} \begin{bmatrix} 2^2 & 0 \\ 0 & 1^2 \end{bmatrix} \begin{bmatrix} 0.8165 & -0.4082 & -0.4082 \\ 0 & -0.7071 & 0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 2.6667 & 1.3333 & 1.3333 \\ 1.3333 & 1.1667 & 0.1667 \\ 1.3333 & 0.1667 & 1.1667 \end{bmatrix} \end{aligned}$$

and that

$$\begin{aligned} \mathbf{A}^T\mathbf{A} &= \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & 0.7071 \end{bmatrix} \begin{bmatrix} 2^2 & 0 \\ 0 & 1^2 \end{bmatrix} \begin{bmatrix} 0.7071 & 0.7071 \\ 0.7071 & 0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 2.5 & -1.5 \\ -1.5 & 2.5 \end{bmatrix}. \end{aligned} \quad (130)$$

Generalized or Pseudoinverse

The inverse of a matrix is defined only for full rank square matrices. The generalization of the inverse for other matrices is called *generalized inverse*, *pseudoinverse*, or *Moore–Penrose inverse* and is denoted by $\mathbf{X}^+$. The pseudoinverse of $\mathbf{A}$ is the unique matrix that satisfies the following four properties:

$$\begin{aligned} \mathbf{A}\mathbf{A}^+\mathbf{A} &= \mathbf{A} & (i) \\ \mathbf{A}^+\mathbf{A}\mathbf{A}^+ &= \mathbf{A}^+ & (ii) \\ (\mathbf{A}\mathbf{A}^+)^T &= \mathbf{A}\mathbf{A}^+ \text{ (symmetry 1)} & (iii) \\ (\mathbf{A}^+\mathbf{A})^T &= \mathbf{A}^+\mathbf{A} \text{ (symmetry 2)} & (iv). \end{aligned} \quad (131)$$

For example, with

$$\mathbf{A} = \begin{bmatrix} 1 & -1 \\ -1 & 1 \\ 1 & 1 \end{bmatrix} \quad (132)$$

we find that the pseudoinverse $\mathbf{A}^+$ is equal to

$$\mathbf{A}^+ = \begin{bmatrix} .25 & -.25 & .5 \\ -.25 & .25 & .5 \end{bmatrix}. \quad (133)$$

This example shows that the product of a matrix and its pseudoinverse does not always give the identity matrix:

$$\begin{aligned} \mathbf{A}\mathbf{A}^+ &= \begin{bmatrix} 1 & -1 \\ -1 & 1 \\ 1 & 1 \end{bmatrix} \begin{bmatrix} .25 & -.25 & .5 \\ -.25 & .25 & .5 \end{bmatrix} \\ &= \begin{bmatrix} 0.3750 & 0.1250 \\ 0.1250 & 0.3750 \end{bmatrix}, \end{aligned} \quad (134)$$

Pseudoinverse and SVD

The SVD is the building block for the Moore–Penrose pseudoinverse because any matrix $\mathbf{A}$ with SVD equal to $\mathbf{P}\Delta\mathbf{Q}^T$ has for pseudoinverse

$$\mathbf{A}^+ = \mathbf{Q}\Delta^{-1}\mathbf{P}^T. \quad (135)$$

For the preceding example, we obtain

$$\begin{aligned} \mathbf{A}^+ &= \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & 0.7071 \end{bmatrix} \begin{bmatrix} 2^{-1} & 0 \\ 0 & 1^{-1} \end{bmatrix} \begin{bmatrix} 0.8165 & -0.4082 & -0.4082 \\ 0 & -0.7071 & 0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 0.2887 & -0.6443 & 0.3557 \\ -0.2887 & -0.3557 & 0.6443 \end{bmatrix}. \end{aligned} \quad (136)$$

Pseudoinverse matrices are used to solve multiple regression and analysis of variance problems.

MAUCHLY TEST

The Mauchly test (or Mauchly's test) assesses the validity of the sphericity assumption that underlies repeated measures analysis of variance (ANOVA). Developed in 1940 by John W. Mauchly, an electrical engineer who codeveloped the first general-purpose computer, the Mauchly test is the default test of sphericity in several common statistical software programs. Provided the data are sampled from a multivariate normal population, a significant Mauchly test result indicates that the assumption of sphericity is untenable. This entry first explains the sphericity assumption and then describes the implementation and computation of the Mauchly test. The entry ends with a discussion of the test's limitations and critiques.

The Sphericity Assumption

The sphericity assumption is the assumption that the difference scores of paired levels of the repeated

measures factor have equal population variance. As with the other ANOVA assumptions of normality and homogeneity of variance, it is important to note that the sphericity assumption refers to population parameters rather than sample statistics. Also worth noting is that the sphericity assumption by definition is always met for designs with only two levels of a repeated measures factor. One need not conduct a Mauchly test on such data, and a test conducted automatically by statistical software will not output *p* values.

Sphericity is a more general form of *compound symmetry*, the condition of equal population covariance (among paired levels) and equal population variance (among levels). Whereas compound symmetry is a sufficient but not necessary precondition for conducting valid repeated measures *F* tests (assuming normality), sphericity is both a sufficient and necessary precondition. Historically, statisticians and social scientists often failed to recognize these distinctions between compound symmetry and sphericity, leading to frequent confusion over the definitions of both, as well as the true statistical assumptions that underlie repeated measures ANOVA. In fact, Mauchly's definition of sphericity is what is now considered compound symmetry, although the Mauchly test nevertheless assesses what is now considered sphericity.

Implementation and Computation

Like any null hypothesis significance test, the Mauchly test assesses the probability of obtaining a value for the test statistic as extreme as that observed given the null hypothesis. In this instance, the null hypothesis is that of sphericity, and the test statistic is Mauchly's *W*. Mathematically, the null hypothesis of sphericity (and alternative hypothesis of nonsphericity) can be written in terms of difference scores

$$H_0 : \sigma_{y_1-y_2}^2 = \sigma_{y_1-y_3}^2 = \sigma_{y_2-y_3}^2 \dots$$

$$H_1 : \sigma_{y_1-y_2}^2 \neq \sigma_{y_1-y_3}^2 \neq \sigma_{y_2-y_3}^2 \dots$$

(for all $k(k-1)/2$ unique difference scores created from k levels of repeated variable y) or in terms of matrix algebra:

$$H_0 : C' \Sigma C = \lambda I$$

$$H_1 : C' \Sigma C = \lambda I,$$

Where C is any $(k-1) \times (k)$ orthonormal coefficient matrix associated with the hypothesized repeated measure effect; C' is the transpose of C ; Σ is the $k \times k$

population covariance matrix; λ is a positive, scalar number; and $\mathbf{I}$ is the $(k - 1) \times (k - 1)$ identity matrix. Mauchly's test statistic, W , can be expressed concisely only in terms of matrix algebra:

$$W = \frac{|\mathbf{C}'\mathbf{S}\mathbf{C}|}{\left[\frac{\text{tr}(\mathbf{C}'\mathbf{S}\mathbf{C})}{k - 1}\right]^{k-1}},$$

where $\mathbf{S}$ is the $k \times k$ sample covariance matrix. One can rely on either an approximate or exact sampling distribution to determine the probability value of an obtained W value. Because of the cumbersome computations required to determine exact p values and the precision of the chi-square approximation, even statistical software packages (e.g., SPSS, an IBM company, formerly called PASW® Statistics) typically rely on the latter. The chisquare approximation is based on the statistic $-(n - 1)dW$ with degrees of freedom (df) = $k(k - 1)/2 - 1$, where

$$d = 1 - \left[\frac{2(k - 1)^2 + (k - 1) + 2}{6(k - 1)(n - 1)} \right].$$

For critical values for the exact distribution, see Nagarsenker and Pillai (1973).

Limitations and Critiques

The Mauchly test is not robust to nonnormality: Small departures from multivariate normality in the population distribution can lead to artificially low or high Type I error (i.e., false positive) rates. In particular, heavy-tailed (leptokurtic) distributions can—under typical sample sizes and significance thresholds—triple or quadruple the number of Type I errors beyond their expected rate. Researchers who conduct a Mauchly test should therefore examine their data for evidence of nonnormality and, if necessary, consider applying normalizing transformations before reconducting the Mauchly test.

Compared with other tests of sphericity, the Mauchly test is not the most statistically powerful. In particular, the *local invariant test* (see Cornell, Young, Seaman, & Kirk, 1992) produces fewer Type II errors (i.e., false negative) than the Mauchly test does. This power difference between the two tests is trivially small for large samples and small k/n ratios but noteworthy for small samples sizes and large k/n ratios. For this reason, some advocate the use of the local invariant test over the Mauchly test.

Finally, some statisticians have called into question the utility of conducting any preliminary test of

sphericity such as the Mauchly test. For repeated measures data sets in the social sciences, they argue, sphericity is almost always violated to some degree, and thus researchers should universally correct for this violation (by adjusting df with the Greenhouse–Geisser and the Huynh–Feldt estimates). Furthermore, like any significance test, the Mauchly test is limited in its utility by sample size: For large samples, small violations of sphericity often produce significant Mauchly test results, and for small samples, the Mauchly test often does not have the power to detect large violations of sphericity. Finally, critics of sphericity testing note that adoption of the df correction tests only when the Mauchly test reveals significant nonsphericity—as opposed to always adopting such df correction tests—does not produce fewer Type I or II errors under typical testing conditions (as shown by simulation research).

Aside from using alternative tests of sphericity or forgoing such tests in favor of adjusted df tests, researchers who collect data on repeated measures should also consider employing statistical models that do not assume sphericity. Of these alternative models, the most common is multivariate ANOVA (MANOVA). Power analyses have shown that the univariate ANOVA approach possesses greater power than the MANOVA approach when sample size is small ($n < k + 10$) or the sphericity violation is not large ($\epsilon > .7$) but that the opposite is true when sample sizes are large and the sphericity violation is large.

MAXIMUM LIKELIHOOD ESTIMATION

Maximum likelihood estimation (MLE) is one of the most commonly used estimation methods. Some features that prediction methods should have are efficiency, unbiasedness, and minimum variance. The method of maximum likelihood (ML) has all of these features and is a very reliable estimator. MLE is also the basis of many statistical methods. In some cases, the likelihood function is mathematically difficult to compute. Nevertheless, parameters that are suitable for many distributions can be estimated with the MLE. This entry discusses general aspects of MLE as well as the ML estimators and their properties.

General Aspects of MLE

MLE was developed by R. A. Fisher in the 1920s. Its main aim is to make observed data *most likely*, that is, to maximize the likelihood function. MLE has an important place in the theory of many statistical methods. Furthermore, many inference methods in statistics are based on MLE, including chi-square test, Bayesian methods, inference with missing data, modeling of random effects, Akaike information criterion, and the Bayesian information criteria.

One of the most important features of the ML method is that the estimators obtained are asymptotically unbiased and efficient. An important disadvantage of the method is that mathematical solutioning of some maximization problems can be difficult in the estimation process.

One of the most reliable ways to predict variables is the MLE. The parameter values most likely to produce the observed data are selected from the MLE. Based on numerous scientific studies, the MLE provides an optimal and reliable estimate for many problems encountered.

The Fisher information matrix appears in MLE as a measure of independency between estimated parameters. The inverse of the Fisher information matrix gives the covariance matrix for the estimation errors of the parameters. As a result of this feature, the orthogonalization of the parameters ensures that the estimates of the parameters are distributed independently from each other. However, diagonalizing the Fisher matrix by linear algebra *locally* or at specific parameter values does not make sense because the parameter values are unknown, that is, they have not yet been estimated.

The MLE is a reasonable choice for an estimator because it is the parameter point for which the observed sample is most likely. There are two inherent disadvantages associated with the general problem of

finding the maximum of a function, and therefore, MLE. The first problem is that of actually finding the global maximum and verifying that, indeed, a global maximum has been found. In many cases, this problem reduces to a simple differential calculus exercise, but, sometimes even for common densities, difficulties do arise. The second problem is that of numerical sensitivity—that is, how sensitive is the estimate to small changes in the data? This problem is a mathematical rather than a statistical problem associated with any maximization procedure. Unfortunately, sometimes a slightly different sample will produce a vastly different MLE.

The following is a real-life example to understand the MLE process. Suppose that four text messages arrive on a person's phone in the morning. However, the person deleted one of the messages carelessly before reading it. If two of the remaining three messages are about monthly bills, what might be a good estimate of k , the total number of monthly bills among the four messages? Frankly, k must be two or three.

$$\frac{\binom{2}{2}\binom{2}{1}}{\binom{4}{3}} = \frac{1}{2}$$

for $k = 2$ and

$$\frac{\binom{3}{2}\binom{1}{1}}{\binom{4}{3}} = \frac{3}{4}$$

for $k = 3$.

If k is chosen to predict the messages, the value that maximizes the probability of obtaining the observed data is obtained as $k = 3$. This estimation is called MLE, and the method that is used to estimate it is ML. Thus, the essential feature of ML is that looking at the sample values and then choosing as our estimates of the unknown parameters the values for which the probability or probability density of getting the sample values is a maximum.

The ML method can also be used to estimate multiple parameters belonging to a population simultaneously. In this case, the values of the parameters that jointly maximize the likelihood function must be found. Therefore, the main feature of the ML method is to look at the sample values and then select the values for which the probability density or probability density of the sample values is maximum as estimates for the unknown parameters.

To summarize, MLE is a method for searching the probability distribution that optimizes the observed data.

Let $X_1, \dots, X_n$ be independent and identically distributed with probability distribution $f(x; \theta)$.

Definition

The likelihood function is defined by

$$\mathcal{L}_n(\theta) = \prod_{i=1}^n f(X_i, \theta). \quad (1)$$

The log-likelihood function is defined by $\ell_n(\theta) = \log \mathcal{L}_n(\theta)$. The likelihood function is the joint density of the data of interest, except that it is treated as a function of the parameter θ . Therefore $\mathcal{L}_n : \theta \rightarrow [0, \infty)$.

The ML estimator, denoted by $\hat{\theta}_n$, is the value of θ that maximizes $\mathcal{L}_n(\theta)$.

Example 1

Suppose that $X_1, \dots, X_n \sim \text{Bernoulli}(p)$. The probability function for Bernoulli(p) is $f(x; p) = p^x (1-p)^{1-x}$ for $x = 0, 1$. The unknown parameter is p . Then

$$\mathcal{L}_n(p) = \prod_{i=1}^n f(X_i; p) = \prod_{i=1}^n p^{X_i} (1-p)^{1-X_i} = p^S (1-p)^{n-S}$$

where $S = \sum_i X_i$. As a consequence,

$$\ell_n(p) = S \log p + (n-S) \log(1-p).$$

Hence, taking the derivative of $\ell_n(p)$ by setting it equal to 0 to find that the ML estimator is $\hat{p}_n = S/n$.

The method of ML can also be used for the simultaneous estimation of several parameters of a given population. In this case, the values of the parameters that jointly maximize the likelihood function must be found.

Example 2

If $X_1, \dots, X_n$ constitutes a random sample of size n from a normal population with the mean μ , and the variance σ^2 , find joint ML estimates of these two parameters.

Since the likelihood function is given by

$$\begin{aligned} \mathcal{L}(\mu, \sigma^2) &= \prod_{i=1}^n f(x_i; \mu, \sigma) \\ &= \left(\frac{1}{\sigma \sqrt{2\pi}} \right)^n e^{-\frac{1}{2\sigma^2} \sum_{i=1}^n (x_i - \mu)^2}. \end{aligned}$$

Partial differentiation of $\mathcal{L}(\mu, \sigma^2)$ with respect to μ and σ^2 yields

$$\frac{\partial [\ln \mathcal{L}(\mu, \sigma^2)]}{\partial \mu} = \frac{1}{\sigma^2} \sum_{i=1}^n (x_i - \mu)$$

and

$$\frac{\partial [\ln \mathcal{L}(\mu, \sigma^2)]}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \sum_{i=1}^n (x_i - \mu)^2.$$

Equating the first of these two partial derivatives to zero and solving for μ , getting

$$\hat{\mu} = \frac{1}{n} \sum_{i=1}^n x_i = \bar{x}$$

and equating the second of these partial derivatives to zero and solving for σ^2 after substituting $\mu = \bar{x}$, then

$$\hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2.$$

Properties of ML Estimators

ML estimator, $\hat{\theta}_n$, has many optimal properties that make it an attractive estimator choice. The main properties of ML estimators are

- consistency
- equivariant
- asymptotically normal distributed
- asymptotically optimal or efficient

If these properties are not met, MLE will not be a good estimator choice.

Efficiency was defined by Fisher in his work in 1922: "The criterion of efficiency is satisfied by those statistics which, when derived from large samples, tend to a normal distribution with the least possible standard deviation" (p. 310). Later, in 1925, the importance of the ML method was emphasized by Fisher: "We shall prove that when an efficient statistic exists, it may be found by the method of MLE" (p. 710).

Evidently, therefore, efficiency was regarded as an essentially asymptotic property. Nowadays, it is said that an estimator is efficient, whatever the sample size, if its variance attains the Cramer-Rao lower bound, and Fisher's property would be described as asymptotic efficiency. In 1922, Fisher defined sufficiency in his work as follows: "A statistic satisfies the criterion of sufficiency when no other statistic which can be calculated from the sample provides any additional information as to the value of the parameter to be estimated" (p. 310).

It is well known that there is a close relation between sufficient statistics and MLE. Furthermore,

likelihood was defined by Fisher in 1922 work as follows: "The likelihood that any parameter (or set of parameters) should have any assigned value (or set of values) is proportional to the probability that if this were so, the totality of observations should be that observed" (p. 310). The method of ML as expounded by Fisher consists of regarding the likelihood as a function of the unknown parameter and obtaining the value of this parameter that makes the likelihood greatest. Such a value is then said to be the ML estimate of the parameter.

Consistency of ML Estimator

The first property is that in the large limit of the number of observation n , the estimate $\hat{\theta}$ goes to the true value θ . This property is essential for an estimator. Consistency of an estimator means that the estimator converges the parameter in probability to the true value.

Definition

Let $X_1, \dots, X_n$ be observations and $\hat{\theta}_n$ is obtained estimator using $(X_1, \dots, X_n)$. $\hat{\theta}_n$ is consistent if $\hat{\theta}_n \rightarrow \theta$, where θ is the true parameter value.

$$P\left\{\left|\hat{\theta}_n - \theta\right| > \varepsilon\right\} \rightarrow 0, \text{ as } n \rightarrow \infty \quad (2)$$

Also, Equation 2 has conditions as shown in Equation 3.

$$E\left\{\left(\hat{\theta}_n - \theta\right)^2\right\} \rightarrow 0, \text{ as } n \rightarrow \infty \quad (3)$$

Proof

According to Chebyshev's inequality, then

$$P\left\{\left|\hat{\theta}_n - \theta\right| \geq \varepsilon\right\} \leq \frac{E\left\{\left(\hat{\theta}_n - \theta\right)^2\right\}}{\varepsilon^2}. \quad (4)$$

Since $E\left\{\left(\hat{\theta}_n - \theta\right)^2\right\} \rightarrow 0$, then

$$0 \leq P\left\{\left|\hat{\theta}_n - \theta\right| \geq \varepsilon\right\} \leq \frac{E\left\{\left(\hat{\theta}_n - \theta\right)^2\right\}}{\varepsilon^2} \rightarrow 0.$$

Therefore, $P\left\{\left|\hat{\theta}_n - \theta\right| > \varepsilon\right\} \rightarrow 0$, as $n \rightarrow \infty$.

Example 3

$(X_1, \dots, X_n)$ are independent and identically distributed Gaussian random variables with distribution $N(\theta, \sigma^2)$.

$$\begin{aligned} f(x; \theta) &= \prod_{k=1}^n f(x_k; \theta) \\ &= \prod_{k=1}^n \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x_k - \theta)^2}{2\sigma^2}\right) \\ &= \frac{1}{(2\pi\sigma^2)^{\frac{n}{2}}} \exp\left(-\frac{\sum_{k=1}^n (x_k - \theta)^2}{2\sigma^2}\right). \end{aligned}$$

The logarithm of both sides of the above equation is taken. Then

$$\log f(x; \theta) = -\frac{n}{2} \log(2\pi\sigma^2) - \frac{\sum_{k=1}^n (x_k - \theta)^2}{2\sigma^2}.$$

Since $\log f(x; \theta)$ is a quadratic concave function of θ , ML estimator is obtained by solving the following equation:

$$\frac{\partial \log f(x; \theta)}{\partial \theta} = \frac{2 \sum_{k=1}^n (x_k - \theta)}{2\sigma^2} = 0.$$

Thus, the ML estimator is $\hat{\theta}_{MLE}(x) = \frac{1}{n} \sum_{k=1}^n x_k$

since

$$E\left\{\left(\hat{\theta}_n - \theta\right)^2\right\} = \text{Var}(\hat{\theta}_n) = \frac{\sigma^2}{n}.$$

Therefore $E\left\{\left(\hat{\theta}_n - \theta\right)^2\right\} \rightarrow 0$. So $\hat{\theta}_n \rightarrow \theta$, $\hat{\theta}_n$ is consistent.

Equivariance of ML Estimator

Theorem

Let $\tau = g(\theta)$ be a one-to-one function of θ . Let $\hat{\theta}_n$ be the ML estimator of θ . Then $\hat{\tau}_n = g(\hat{\theta}_n)$ is the ML estimator of τ .

Proof

Let $h = g^{-1}$ denote the inverse of g . Then $\hat{\theta}_n = h(\hat{\tau}_n)$. For any τ , $\mathcal{L}(\tau) = \prod_i f(x_i; h(\tau)) = \prod_i f(x_i; \theta) = \mathcal{L}(\theta)$ where $\theta = h(\tau)$. Hence, for τ , $\mathcal{L}_n(\tau) = \mathcal{L}(\theta) \leq \mathcal{L}(\hat{\theta}) = \mathcal{L}_n(\hat{\tau})$.

Example 4

Let $X_1, \dots, X_n \sim N(0, 1)$. The ML estimator for θ is $\hat{\theta}_n = \bar{X}_n$. Let $\tau = e^\theta$. Then, the ML estimator for τ is $\hat{\tau} = e^{\hat{\theta}} = e^{\bar{X}}$.

Asymptotic Normality of ML Estimator

It is known that $\hat{\theta}_n$ is approximately normally distributed. Several definitions have been proffered to explain these features.

Definition

The score function is defined to be

$$s(X; \theta) = \frac{\partial \log f(X; \theta)}{\partial \theta}. \quad (5)$$

The Fisher information is defined to be

$$\begin{aligned} I_n(\theta) &= V_0 \left(\sum_{i=1}^n s(X_i; \theta) \right) \\ &= \sum_{i=1}^n V_0(s(X_i; \theta)). \end{aligned} \quad (6)$$

For simplification $I_n(\theta)$, for $n=1$, replace $I_1(\theta)$ with $I(\theta)$.

Theorem

$$\begin{aligned} I_n(\theta) &= nI(\theta) \text{ and} \\ I(\theta) &= -E_{\theta} \left(\frac{\partial^2 \log f(X; \theta)}{\partial^2 \theta^2} \right) \\ &= -\int \left(\frac{\partial^2 \log f(x; \theta)}{\partial^2 \theta^2} \right) f(x; \theta) dx \end{aligned} \quad (7)$$

Asymptotic Normality of the ML Estimator

Under appropriate regularity conditions, the following equations hold:

1. Let $se = \sqrt{1/I_n(\theta)}$. Then,

$$\frac{(\hat{\theta}_n - \theta)}{se} \rightarrow N(0, 1) \quad (8)$$

2. Let $\widehat{se} = \sqrt{1/I_n(\hat{\theta}_n)}$. Then,

$$\frac{(\hat{\theta}_n - \theta)}{\widehat{se}} \rightarrow N(0, 1) \quad (9)$$

Theorem says that the distribution of ML estimator can be approximated with $N(\theta; \widehat{se}^2)$. Therefore, an asymptotic confidence interval can be calculated.

Theorem

Let

$$C_n = \left(\hat{\theta}_n - z_{\alpha/2} \widehat{se} \leq \theta \leq \hat{\theta}_n + z_{\alpha/2} \widehat{se} \right) \quad (10)$$

Then $P_{\theta}(\theta \in C_n) \rightarrow 1 - \alpha$ as $n \rightarrow \infty$.

Proof

Let Z denote a standard normal random variable. Then,

$$\begin{aligned} P_{\theta}(\theta \in C_n) &= P_{\theta} \left(\hat{\theta}_n - z_{\alpha/2} \widehat{se} \leq \theta \leq \hat{\theta}_n + z_{\alpha/2} \widehat{se} \right) \\ &= P_{\theta} \left(-z_{\alpha/2} \leq \frac{\hat{\theta}_n - \theta}{\widehat{se}} \leq z_{\alpha/2} \right) \\ &\rightarrow P \left(-z_{\alpha/2} < Z < z_{\alpha/2} \right) = 1 - \alpha, \end{aligned}$$

For $\alpha = 0.05$, $z_{\alpha/2} = 1.96 \approx 2$, so

$$\hat{\theta}_n \mp 2\widehat{se}. \quad (11)$$

When an explanation is read about a poll, a sentence like the following is usually seen: the questionnaire is accurate to within one point, 95% confidence interval of the form $\hat{\theta}_n \mp 2\widehat{se}$.

Example 5

Let $X_1, \dots, X_n \sim \text{Poisson}(\lambda)$. Then $\hat{\lambda}_n = \bar{X}_n$ and some calculations show that $I_1(\lambda) = 1/\lambda$, so

$$\widehat{se} = \frac{1}{\sqrt{nI_1(\hat{\lambda}_n)}} = \sqrt{\frac{\hat{\lambda}_n}{n}}.$$

Therefore, an approximate $1 - \alpha$ confidence interval for λ is $\hat{\lambda}_n \mp z_{\alpha/2} \sqrt{\frac{\hat{\lambda}_n}{n}}$.

Efficiency of ML Estimator

Suppose that $X_1, \dots, X_n \sim N(0, \sigma^2)$. The ML estimator is $\hat{\theta}_n = \bar{X}_n$. Another reasonable estimator is the sample median $\tilde{\theta}_n$. The ML estimator satisfies

$$\sqrt{n}(\hat{\theta}_n - \theta) \rightarrow N(0, \sigma^2).$$

It can be proved that the median satisfies

$$\sqrt{n}(\tilde{\theta}_n - \theta) \rightarrow N\left(0, \sigma^2 \frac{\pi}{2}\right).$$

This means that the median converges to the right value but has a larger variance than the ML estimator.

More generally, consider two estimators T_n and U_n and suppose that

$$\sqrt{n}(T_n - \theta) \rightarrow N(0, t^2)$$

and that

$$\sqrt{n}(U_n - \theta) \rightarrow N(0, u^2).$$

Asymptotic relative efficiency of U is defined as T by $ARE(U, T) = t^2 / u^2$. In the normal example, $ARE(\tilde{\theta}_n, \hat{\theta}_n) = 2 / \pi = 0.63$. The interpretation is that if the median is used, only about 63% of the available data will be used.

Theorem

If $\hat{\theta}_n$ is the ML estimator and $\tilde{\theta}_n$ is any other estimator then

$$ARE(\tilde{\theta}_n, \hat{\theta}_n) \leq 1.$$

Thus, the ML estimator has the smallest (asymptotic) variance and ML estimator is said to be efficient or asymptotically optimal.

This result is predicated upon the assumed model being correct. If the model is wrong, the ML estimator may no longer be optimal.

ML Estimators of Some Distributions

ML estimators are calculated based on the distributions appropriate to our data set. For this reason, likelihood estimators of some important distributions are provided in the following subsections.

Poisson Distribution

Let's consider the Poisson distribution as an example of the MLE. This discrete Poisson distribution describes the probability of repeating an event for a given number of times within a given time or spatial field. For example, the number of vehicles passing a certain point in a 5-minute period is a random variable that fits the Poisson distribution. The general representation of the Poisson distribution is as follows:

$$f(x) = \frac{e^{-\lambda} \lambda^x}{x!} \quad (12)$$

where x represents number of events and λ represents number of incident occurrences. The goal is to find the ML estimator for λ . Let's take the mathematical representation of the Poisson distribution and calculate the likelihood equation for n observations.

$$\begin{aligned} \mathcal{L}(\lambda) &= f(x_1)f(x_2)\dots f(x_n) \\ &= \frac{e^{-\lambda} \lambda^{x_1}}{x_1!} \frac{e^{-\lambda} \lambda^{x_2}}{x_2!} \dots \frac{e^{-\lambda} \lambda^{x_n}}{x_n!} \\ &= \frac{e^{-n\lambda} \lambda^{\sum x_i}}{\prod x_i!} \end{aligned}$$

Then, find the log-likelihood function by taking the two-sided logarithm.

$$\ln(\mathcal{L}(\lambda)) = -n\lambda + \sum x_i \ln \lambda - \ln \prod x_i!$$

Take the derivative of the log-likelihood function and set it equal to zero.

$$\frac{\partial \ln(\mathcal{L}(\lambda))}{\partial \lambda} = -n + \sum x_i \frac{1}{\lambda} = 0$$

If the above equation is solved according to λ ,

$$\hat{\lambda} = \frac{\sum x_i}{n}.$$

Thus, the ML method finds the estimator of λ as the sample mean of x .

Exponential Distribution

Let's look at exponential distribution as another example. This continuous distribution describes the time between occurrences in a Poisson-type process in which events repeat at a certain constant rate. For example, the time elapsed between the vehicles passing randomly from a certain point is a random variable that fits the exponential distribution.

The probability density function of the exponential distribution is:

$$\begin{aligned} f(x) &= \left(\frac{1}{\theta}\right) e^{-x/\theta} \quad \text{for } X > 0 \\ &= 0 \quad \text{for } X \leq 0 \quad \text{çin} \end{aligned} \quad (13)$$

where x represents the time and θ represents rate variable of the distribution. Now, let's find ML estimator of θ . Firstly, find the likelihood function for n observations.

$$\mathcal{L}(\theta) = \frac{1}{\theta^n} \exp\left(\frac{-\sum x_i}{\theta}\right)$$

The log-likelihood function is derivatized and set to zero.

$$\begin{aligned} \ln(\mathcal{L}(\theta)) &= -n \ln \theta - \sum \frac{x_i}{\theta} \\ \frac{\partial \ln(\mathcal{L}(\theta))}{\partial \theta} &= -\frac{n}{\theta} + \sum \frac{x_i}{\theta^2} = 0 \\ \tilde{\theta} &= \frac{\sum x_i}{n} \end{aligned}$$

This means when sample size is n , the ML estimator of θ is $\tilde{\theta} = \sum x_i / n$.

Normal Distribution

Now, estimate $Y_i = \beta_1 + \beta_2 X_i + u_i$, the regression equation by the MLE. The error term is assumed to be independent and identically normally distributed ($u_i \sim N(0, \sigma^2)$). Also $X \sim N(\mu, \sigma^2)$ and the probability density function of X is as follows:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{1}{2} \frac{(x-\mu)^2}{\sigma^2}\right\}.$$

Since the error term is normally distributed $u_i \sim N(0, \sigma^2)$, then $Y_i \sim N(\beta_1 + \beta_2 X_i, \sigma^2)$. In other words, Y_i values distributed normally with $\beta_1 + \beta_2 X_i$ mean and σ^2 variance. Accordingly, the probability density function of a single Y is

$$f(Y_i | \beta_1 + \beta_2 X_i, \sigma^2) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{1}{2} \frac{(Y_i - \beta_1 - \beta_2 X_i)^2}{\sigma^2}\right\}. \quad (14)$$

The joint probability density function of independent and identically Y_i $i \in 1, 2, \dots, n$ is:

$$f(Y_1 | \beta_1 + \beta_2 X_1, \sigma^2) f(Y_2 | \beta_1 + \beta_2 X_2, \sigma^2) \dots f(Y_n | \beta_1 + \beta_2 X_n, \sigma^2). \quad (15)$$

Substituting Equation 14 in Equation 15 for each Y_i and X_i in the observation, the likelihood function is found.

$$\mathcal{L}(\beta_1, \beta_2, \sigma^2) = \frac{1}{\sigma^n \sqrt{2\pi}^n} \exp\left\{-\frac{1}{2} \sum_{i=1}^n \frac{(Y_i - \beta_1 - \beta_2 X_i)^2}{\sigma^2}\right\}$$

Taking the natural logarithm of this equation, the log-likelihood function is obtained:

$$\ln(\mathcal{L}(\beta_1, \beta_2, \sigma^2)) = -n \ln(\sigma) - \frac{n}{2} \ln(2\pi) - \frac{1}{2} \sum_{i=1}^n \frac{(Y_i - \beta_1 - \beta_2 X_i)^2}{\sigma^2}.$$

Maximizing $\ln(\mathcal{L}(\beta_1, \beta_2, \sigma^2))$ means minimizing the last term. This process is the same as the least squares approach. If the partial derivatives of the log likelihood function with respect to β_1 , β_2 , and σ^2 are taken, the following equations are found:

$$\frac{\partial \ln(\mathcal{L}(\beta_1, \beta_2, \sigma^2))}{\partial \beta_1} = -\frac{1}{\sigma^2} \sum_{i=1}^n (Y_i - \beta_1 - \beta_2 X_i) (-1)$$

$$\frac{\partial \ln(\mathcal{L}(\beta_1, \beta_2, \sigma^2))}{\partial \beta_2} = -\frac{1}{\sigma^2} \sum_{i=1}^n (Y_i - \beta_1 - \beta_2 X_i) (-X_i)$$

$$\frac{\partial \ln(\mathcal{L}(\beta_1, \beta_2, \sigma^2))}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \sum_{i=1}^n (Y_i - \beta_1 - \beta_2 X_i)^2$$

After these equations are equal to zero and solved together, ML estimators are obtained:

$$\begin{aligned} \beta_1 &= \bar{Y} - \beta_2 \bar{X} \\ \beta_2 &= \frac{\sum x_i y_i}{\sum x_i^2} \\ \sigma^2 &= \frac{\sum \hat{u}_i^2}{n} \end{aligned}$$

As seen under the normality assumption of u_i , the ML and least square estimators of the β coefficients are the same. On the other hand, estimates of σ^2 are different.

Least square estimator of σ^2 :

$$\hat{\sigma}^2 = \frac{\sum \hat{u}_i^2}{n-2}$$

The MLE of σ^2 :

$$\hat{\sigma}^2 = \frac{\sum \hat{u}_i^2}{n}$$

MBESS

MBESS is an R package that was developed primarily to implement important but nonstandard methods for the behavioral, educational, and social sciences. Although originally an acronym for Methods for the Behavioral, Educational, and Social Sciences, MBESS has broader purposes and is now treated as its own name, pronounced *m-bess*. The generality and applicability of many of the functions contained within

MBESS have allowed the package to be used within a variety of other disciplines. Both MBESS and R are open source and freely available from The R Project's Comprehensive R Archive Network. The MBESS Comprehensive R Archive Network website contains the reference manual, source code files, and binaries files. MBESS (and R) is available for Macintosh, Windows, and Unix/Linux operating systems.

The major categories of functions most used within MBESS are used for the (a) estimation of effect sizes (standardized and unstandardized), (b) confidence interval formation based on central and noncentral distributions (t , F , and χ^2), (c) sample size planning from the accuracy in parameter estimation and power analytic perspectives, and (d) miscellaneous functions that allow the user to easily interact with R for analyzing data. Most MBESS functions require only summary statistics, an advantage to requiring raw data when using results from reported studies. MBESS thus allows researchers to compute effect sizes and confidence intervals based on summary statistics (e.g., from articles), which facilitates using previously reported information (e.g., for calculating effect sizes to be included in meta-analyses) or if one is primarily using a program other than R to analyze data but still would like to use the functionality of MBESS.

MBESS, like R, is based on a programming environment instead of a point-and-click interface for the analysis of data. Because of the necessity to write code in order for R to implement functions (such as the functions contained within the MBESS package), a resulting benefit is *reproducible research*, in the sense that a record exists of the exact analyses performed with all options and subsamples denoted. Having a record of the exact analyses, by way of a script file, that were performed allows the data analyst to (a) respond to inquiries regarding the exact analyses, algorithms, and options, (b) modify code for similar analyses on the same or future data, and (c) provide code and data so that others can replicate the published results. Many novel statistical techniques are implemented in R and in many ways R has become necessary for cutting-edge developments in statistics and measurement.

MBESS was developed by Ken Kelley with its first public release in May 2006 and has since incorporated functions contributed by others and used by other packages. Only minimal experience with R is required in order to use many of the functions contained within the MBESS package.

McDONALD'S OMEGA HIERARCHICAL

Omega hierarchical, named by Roderick McDonald, is a measure of the extent to which the total score on a test or scale reliably measures a single, general construct that influences all of the total score's components (typically, scores on individual items). As such, omega hierarchical can be considered a type of internal consistency reliability (or composite reliability) measure. Unlike the more commonly reported Cronbach's coefficient alpha, omega hierarchical is an appropriate reliability estimate when a test has a multidimensional structure (i.e., there are multiple systematic influences on the item responses), but a researcher's interest lies in the reliability of an overall score for the test. Reliability estimation is fundamental to research methods because reliability quantifies the quality of a measurement; without accurate measurement, research results are not trustworthy.

Reliability is formally defined as the proportion of a score's *true score* variance relative to total variance, where an individual's true score is the hypothetical expected value of the test score obtained as the average score the individual would obtain across an infinite number of independent test administrations. Classical

reliability measures, such as coefficient alpha, are not based on any claims about the number or nature of hypothetical psychological constructs determining an individual's true score. However, researchers are most often interested in how well a test score represents a test taker's position on a construct that the test was designed to measure (i.e., the *target construct*). When this construct is the only systematic influence on a test's total score, that is, the test is unidimensional, then coefficient alpha estimates the proportion of total score variance due to that construct, that is, the reliability of the total score with respect to the measurement of the target construct.

Yet, many tests are developed so that the total score is meant to be a measurement of a broad target construct that is common to all items in the test, but the test's internal structure is multidimensional such that this target construct is not the only systematic influence on the total score. In this situation, coefficient alpha is likely to be an inflated estimate of the proportion of total score variance that is due to the target construct; thus, coefficient alpha is a misleading reliability estimate for the total score of a multidimensional test. Instead, the proportion of total score variance due to a target construct (i.e., the reliability of the total score as a measure of the construct) can be expressed as a function of the parameters of a measurement model (i.e., a factor analysis model) that has been specified to situate the target construct as a common factor within the test's internal structure. When the correct population measurement model for a multidimensional test's internal structure is a hierarchical factor model (i.e., a *bifactor model*), then omega hierarchical can be calculated from the model's parameters to represent the proportion of total score variance that is due to a broad, general factor that influences all of the test's items, thereby providing an appropriate measure of the reliability of the total score as a measure of a single construct that influences all items in a multidimensional test.

Therefore, to calculate omega hierarchical, one must first fit a bifactor model to the item response data. A bifactor model is characterized by a *general factor* that directly influences all of the items along with a set of two or more *specific factors* (also known as *group factors*), each of which directly influences only a subset of items; the specific factors are orthogonal to (i.e., uncorrelated with) the general factor and account for covariances among the items that remain over and above the influence of the general factor. The general factor can be considered a representation of the target construct that influences all items in the test, while the specific factors represent systematic sources of multidimensionality. For estimating omega hierarchical, the bifactor

model can be estimated with confirmatory factor analysis, although an exploratory factor analysis (along with a bifactor rotation) or multidimensional item response theory approach is also possible. With either exploratory factor analysis or confirmatory factor analysis, it may be important to treat item response data as categorical by fitting the bifactor model to the polychoric correlations among the items (e.g., for items with five or fewer response categories). The multidimensional item response theory approach fits the model directly to the categorical item response frequency data, but the discrimination parameter estimates need to be transformed to the common factor model metric before omega hierarchical can be calculated.

Omega hierarchical is then a function of the associations between the items and the general factor (i.e., the general factor loadings), providing an index of the proportion of total score variance that is due to the general factor. An equation for omega hierarchical is:

$$\omega_h = (I = 1) \lambda_{gi}^2 / \sigma_X^2$$

$$\omega_h = \frac{\left(\sum_{i=1}^I \lambda_{gi}^2 \right)}{\sigma_X^2}$$

where $i = 1, \dots, I$ index items, λ_{gi} is the factor loading for item i on the general factor, and σ_X^2 is the variance of the test total score. The total score variance can be estimated from either the model-implied total variance (i.e., the sum of the elements of the fitted covariance matrix) or the observed variance of the total score.

Omega hierarchical is not to be confused with a similar reliability estimate often simply referred to as *omega* or *coefficient omega*. Whereas omega hierarchical is a function of the parameters of a bifactor model, coefficient omega is a function of the parameters of a one-factor model. Both coefficient omega and omega hierarchical represent the proportion of total score variance that is due to a target construct that influences all items in the test, but coefficient omega assumes that the target construct is the only systematic influence on the item responses (i.e., the test is unidimensional), whereas omega hierarchical assumes that the target construct is represented by the general factor of a bifactor model along with systematic influences on subsets of items (i.e., specific factors) that are orthogonal to the target construct. Furthermore, the bifactor model is only one potential multidimensional structure for a test; alternative reliability estimates may need to be developed for tests conforming to other multidimensional structures. Therefore, obtaining a reliability estimate that accurately represents the proportion of test score variance that is due to a single construct that

is common to all of the test items entails specifying the correct model for the test's internal structure.

McNEMAR'S TEST

McNemar's test, also known as a *test of correlated proportions*, is a nonparametric test used with dichotomous nominal or ordinal data to determine whether two sample proportions based on the same individuals are equal. McNemar's test is used in many fields, including the behavioral and biomedical sciences. In short, it is a test of symmetry between two related samples based on the chi-square distribution with 1 degree of freedom (*df*).

McNemar's test is unique in that it is the only test that can be used when one or both conditions being studied are measured using the nominal scale. It is often used in before–after studies, in which the same individuals are measured at two times, a pretest–posttest, for example. McNemar's test is also often used in matched-pairs studies, in which similar people are exposed to two different conditions, such as a case–control study. This entry details the McNemar's test formula, provides an example to illustrate the test, and examines its application in research.

Formula

McNemar's test, in its original form, was designed only for dichotomous variables (i.e., yes–no, right–wrong,

effect–no effect) and therefore gives rise to proportions. McNemar's test is a test of the equality of these proportions to one another given the fact that they are based in part on the same individual and therefore correlated. More specifically, McNemar's test assesses the significance of any observed change while accounting for the dependent nature of the sample. To do so, a fourfold table of frequencies must be set up to represent the first and second sets of responses from the same or matched individuals. This table is also known as a 2×2 contingency table and is illustrated in Table 1.

In this table, Cells *A* and *D* represent the discordant pairs, or individuals whose response changed from the first to the second time. If an individual changes from + to –, he or she is included in Cell *A*. Conversely, if the individual changes from – to +, he or she is tallied in Cell *D*. Cells *B* and *C* represent individuals who did not change responses over time, or pairs that are in agreement. The main purpose of McNemar's test is determine whether the proportion of individuals who changed in one direction (+ to –) is significantly different from that of individuals who changed in the other direction (– to +).

When one is using McNemar's test, it is unnecessary to calculate actual proportions. The difference between the proportions algebraically and conceptually reduces to the difference between the frequencies given in *A* and *D*. McNemar's test then assumes that *A* and *D* belong to a binomial distribution defined by

$$n = A + D, p = .05, \text{ and } q = .05.$$

Based on this, the expectation under the null hypothesis would be that $\frac{1}{2}(A + D)$ cases would change in one direction and $\frac{1}{2}(A + D)$ cases would change in the other direction. Therefore, $H_0: A = D$. The χ^2 formula,

$$\chi^2 = \sum \frac{(O_i - E_i)^2}{E_i},$$

where O_i = observed number of cases in the *i*th category and E_i = expected number of cases in the *i*th category under H_0 , converts into

$$\chi^2 = \frac{(A - (A + D)/2)^2}{(A + D)/2} + \frac{(D - (A + D)/2)^2}{(A + D)/2}$$

and then factors into

$$\chi^2 = \frac{(A - D)^2}{A + D} \text{ with } df = 1.$$

Table 1 Fourfold Table for Use in Testing Significance of Change

<i>Before</i>	<i>After</i>	
	–	+
+	A	B
–	C	D

This is McNemar's test formula. The sample distribution is distributed approximately as chi-square with 1 *df*.

Correction for Continuity

The approximation of the sample distribution by the chi-square distribution can present problems, especially if the expected frequencies are small. This is because the chi-square is a continuous distribution whereas the sample distribution is discrete. The correction for continuity, developed by Frank Yates, is a method for removing this source of error. It requires the subtraction of 1 from the absolute value of the difference between *A* and *D* prior to squaring. The subsequent formula, including the correction for continuity, becomes

$$\chi^2 = \frac{(|A - D| - 1)^2}{A + D} \text{ with } df = 1.$$

Small Expected Frequencies

When the expected frequency is very small ($\frac{1}{2}(A + D) < 5$), the binomial test should be used instead.

Example

Suppose a researcher was interested in the effect of negative political campaign messages on voting behavior. To investigate, the researcher uses a before–after

Table 2 Form of Table to Show Subjects' Change in Voting Decision in Response to Negative Campaign Ad

<i>Before Campaign Ad</i>	<i>After Campaign Ad</i>	
	<i>No Vote</i>	<i>Yes Vote</i>
Yes vote	yn	yy
No vote	nn	ny

design in which 65 subjects are polled twice on whether they would vote for a certain politician: before and after viewing a negative campaign ad discrediting that politician. The researcher hypothesizes that the negative campaign message will reduce the number of individuals who will vote for the candidate targeted by the negative ad. The data are recorded in the form shown in Table 2. The hypothesis test follows; the data are entirely artificial.

Statistical Test

McNemar's test is chosen to determine whether there was a significant change in voter behavior. McNemar's test is appropriate because the study uses two related samples, the data are measured on a nominal scale, and the researcher is using a before–after design. McNemar's test formula as it applies to Table 2 is shown below.

$$\chi^2 = \frac{(yn - ny)^2}{yn + ny} \text{ with } df = 1.$$

With the correction for continuity included, the formula becomes

$$\chi^2 = \frac{(|yn - ny| - 1)^2}{yn + ny}.$$

Hypotheses

H_0 : For those subjects who change, the probability that any individual will change his or her vote from yes to no after being shown the campaign ad (that is, P_{yn}) is equal to the probability that the individual will change his or her vote from no to yes (that is, P_{ny}), which is equal to $\frac{1}{2}$. More specifically,

$$H_0 : P_{yn} = P_{ny} = \frac{1}{2}.$$

H_1 : For those subjects who change, the probability that any individual will change his or her vote from yes to no after being shown the negative campaign ad will be significantly greater than the probability that the individual will change his or her vote from no to yes. In other words,

$$H_1 : P_{yn} > P_{ny}.$$

Significance Level

Let $\alpha = .01$, $N = 65$, the number of individuals polled before and after the campaign ad was shown.

Sampling Distribution

The sampling distribution of χ^2 as computed by McNemar's test is very closely approximated by the chi-square distribution with $df = 1$. In this example, H_1 predicts the direction of the difference and therefore requires a one-tailed rejection region. This region consists of all the χ^2 values that are so large they only have a 1% likelihood of occurring if the null hypothesis is true. For a one-tailed test, the critical value with $p < .01$ is 7.87944.

Calculation and Decision

The artificial results of the study are shown in Table 3. The table shows that 30 subjects changed their vote from yes to no (yn) after seeing the negative campaign ad, and 7 subjects changed their vote from no to yes (ny).

The other two cells, $yy = 11$ and $nn = 17$, represent those individuals who did not change their vote after seeing the ad.

For these data,

$$\chi^2 = \frac{(yn - ny)^2}{yn + ny} = \frac{(30 - 7)^2}{(30 + 7)} = \frac{(23)^2}{37} = 14.30.$$

Including the correction for continuity:

$$\begin{aligned}\chi^2 &= \frac{(|yn - ny - 1|)^2}{yn + ny} = \frac{(|30 - 7| - 1)^2}{30 + 7} \\ &= \frac{(22)^2}{37} = 13.08.\end{aligned}$$

The critical χ^2 value for a one-tailed test at $\alpha = .01$ is 7.87944. Both 14.30 and 13.08 are greater than 7.87944; therefore, the null hypothesis is rejected. These results support the researcher's hypothesis that negative campaign ads significantly decrease the number of individuals willing to vote for the targeted candidate.

Application

McNemar's test is valuable to the behavioral and biomedical sciences because it gives researchers a way to

Table 3 Subjects' Voting Decision Before and After Seeing Negative Campaign Ad

Before Campaign Ad	After Campaign Ad	
	No Vote	Yes Vote
Yes vote	30	11
No vote	17	7

test for significant effects in dependent samples using nominal measurement. It does so by reducing the difference between proportions to the difference between discordant pairs and then applying the binomial distribution. It has proven useful in the study of everything from epidemiology to voting behavior, and it has been modified to fit more specific situations, such as misclassified data, improved sample size estimations, multivariate samples, and clustered matched-pair data.

MCP-Mod

See Multiple Comparison Procedures With Modeling Techniques

MEAN

The mean is a parameter that measures the central location of the distribution of a random variable and is an important statistic that is widely reported in scientific literature. Although the arithmetic mean is the most commonly used statistic in describing the central location of the sample data, other variations of it, such as the truncated mean, the interquartile mean, and the geometric mean, may be better suited in a given circumstance. The characteristics of the data dictate which one of them should be used. Regardless of which mean is used, the sample mean remains a random variable. It varies with each sample that is taken from the same population. This entry discusses the use of mean in probability and statistics, differentiates between the arithmetic mean and its variations, and examines how to determine its appropriateness to the data.

Use in Probability and Statistics

In probability, the mean is a parameter that measures the central location of the distribution of a random variable. For a real-valued random variable, the mean, or more appropriately the population mean, is the expected value of the random variable. That is to say, if one observes the random variable numerous times, the observed values of the random variable would converge in probability to the mean. For a discrete random variable with a probability function $p(y)$, the expected value exists if

$$\sum_y yp(y) < \infty, \quad (1)$$

where y is the values assigned by the random variable. For a continuous random variable with a probability density function $f(y)$, the expected value exists if

$$\int_{-\infty}^{\infty} |y| f(y) dy < \infty. \quad (2)$$

Comparing Equation 1 with Equation 2, one notices immediately that the $f(y)dy$ in Equation 2 mirrors the $p(y)$ in Equation 1, and the integration in Equation 2 is analogous to the summation in Equation 1.

The above definitions help to understand conceptually the expected value, or the population mean. However, they are seldom used in research to derive the population mean. This is because in most circumstances, either the size of the population (discrete random variables) or the true probability density function (continuous random variables) is unknown, or the size of the population is so large that it becomes impractical

to observe the entire population. The population mean is thus an unknown quantity.

In statistics, a sample is often taken to estimate the population mean. Results derived from data are thus called *statistics* (in contrast to what are called *parameters* in populations). If the distribution of a random variable is known, a probability model may be fitted to the sample data. The population mean is then estimated from the model parameters. For instance, if a sample can be fitted with a normal probability distribution model with parameters μ and σ , the population mean is simply estimated by the parameter μ (and σ^2 as the variance). If the sample can be fitted with a *Gamma distribution* with parameters α and β , the population mean is estimated by the product of α and β (i.e., $\alpha\beta$), with $\alpha\beta^2$ as the variance. For an exponential random variable with parameter β , the population mean is simply the β , with β^2 as the variance. For a chi-square (χ^2) random variable with ν degrees of freedom, the population mean is ν , with 2ν being the variance.

Arithmetic Mean

When the sample data are not fitted with a known probability model, the population mean is often inferred from the sample mean, a common practice in applied research. The most widely used sample mean for estimating the population mean is the arithmetic mean, which is calculated as the sum of the observed values of a random variable divided by the number of observations in the sample.

Formally, for a sample of n observations, $x_1, x_2, \dots, x_n$ on a random variable X , the arithmetic mean ($\bar{x}$) of the sample is defined as

$$\bar{x} = \frac{1}{n}(x_1 + x_2 + \dots + x_n) = \frac{1}{n} \sum_{i=1}^n x_i, \quad (3)$$

where the notation $\sum_{i=1}^n$ is a succinct representation of the summation of all values from the first to the last observation of the sample. For example, a sample consisting of five observations with values of 4, 5, 2, 6, and 3 has a mean 4 [= (4 + 5 + 2 + 6 + 3)/5] according to the above definition. A key property of the mean as defined above is that the sum of deviations from it is zero.

If data are grouped, the sample mean can no longer be constructed from each individual measurement. Instead, it is defined using the midvalue of each group interval (x_j) and the corresponding frequency of the group (f_j):

$$\bar{x} = \frac{1}{n} \sum_{j=1}^m f_j x_j, \quad (4)$$

where m is the number of groups, and n is the total number of observations in the sample. In Equation 4, $f_j x_j$ is the total value for the j th group. A summation of the values of all groups is then the grand total of the sample, which is equivalent to the value obtained through summation, as defined in Equation 3. For instance, a sample of ($n =$) 20 observations is divided into three groups. The intervals for the three groups are 5 to 9 ($x_1 = 7$), 10 to 14 ($x_2 = 12$), and 15 to 19 ($x_3 = 17$), respectively. The corresponding frequency for each group is ($f_1 =$) 6, ($f_2 =$) 5, and ($f_3 =$) 9. The sample mean according to Equation 4 is then

$$\bar{x} = \frac{7 * 6 + 12 * 5 + 17 * 9}{20} = 12.75.$$

Notice that in Equation 3, we summed up the values of all individual observations before arriving at the sample mean. The summation process is an arithmetic operation on the data. This requires that the data be continuous, that is, they must be either in interval or in ratio scale. For ordinal data, the arithmetic mean is not always the most appropriate measure of the central location; the median is, because it does not require the summation operation.

Notice further that in Equation 3, each observation is given an equal weight. Consequently, the arithmetic mean is highly susceptible to extreme values. Extreme low values would underestimate the mean, while extreme high values would inflate the mean. One must keep this property of the sample arithmetic mean in mind when using it to describe research results.

Because the arithmetic mean is susceptible to variability in the sample data, it is often insufficient to report only the sample mean without also showing the sample standard deviation. Whereas the mean describes the central location of the data, the standard deviation provides information about the variability of the data. Two sets of data with the same sample mean, but drastically different standard deviations, inform the reader that either they come from two different populations or they suffer from variability in quality control in the data collection process. Therefore, by reporting both statistics, one informs the reader of not only the quality of the data but also the appropriateness of using these statistics to describe the data, as well as the appropriate choice of statistical methods to analyze these data subsequently.

Appropriateness

Whether the mean is an appropriate or inappropriate statistic to describe the data is best illustrated by examples of some highly skewed sample data, such as data on the salaries of a corporation, on the house

prices in a region, on the total family income in a nation, and so forth. These types of social economic data are often distorted by a few high-income earners or a few high-end properties. The mean is thus an inappropriate statistic to describe the central location of the data, and the median would be a better statistic for the purpose. On the other hand, if one is interested in describing the height or the test score of students in a school, the sample mean would be a good description of the central tendency of the population as these types of data often follow a unimodal symmetric distribution.

Variations

Extreme values in a data set, if not inherent in a population, are often erroneous and may have either human or instrumental causes. These so-called outliers are therefore artifacts. In order to better estimate the population mean when extreme values occur in a sample, researchers sometimes order the observations in a sample from the smallest to the largest in value and then remove an equal percentage of observations from both the high end and the low end of the data range before applying the arithmetic mean definition to the sample mean. An example is the awarding of a performance score to an athlete in a sport competition. Both the highest and the lowest scores given by the panel of judges are often removed before a final mean score is awarded. This variation of the arithmetic mean is called the *truncated* (or *trimmed*) *mean*.

Suppose that n observations, $x_1, x_2, \dots, x_n$, are obtained from a study population and α percentage of data points are removed from either end of the data range. The truncated mean ($\bar{x}_T$) for the sample is then

$$\begin{aligned}\bar{x}_T &= \frac{1}{n(1-2\alpha)}(x_{1+\alpha n} + x_{2+\alpha n} + \dots + x_{n-\alpha n}) \\ &= \frac{1}{n(1-2\alpha)} \sum_{i=1+\alpha n}^{n-\alpha n} x_i.\end{aligned}\quad (5)$$

In reporting the truncated mean, one must give the percentage of the removed data points in relation to the total number of observations, that is, the value of α , in order to inform the reader how the truncated mean is arrived at. Even with the removal of some extreme values, the truncated mean is still not immune to problematic data, particularly if the sample size n is small.

If the entire first quartile and the entire last quartile of the data points are removed after the observations of the data set are ordered from the smallest to the largest in value, the truncated mean of the sample is called the *interquartile mean*. The interquartile mean can be calculated as follows:

$$\bar{x} = \frac{2}{n} \sum_{i=(n/4)+1}^{3n/4} x_i, \quad (6)$$

where the i value beneath Σ indicates that the summation starts from the $(n/4 + 1)$ th observation of the data set, and the value above Σ signals that the summation ends at the $(3n/4)$ th observation. The 2 above n normalizes the interquartile mean to the full n observations of the sample.

The mean is frequently referred to as the *average*. This interchangeable usage sometimes confuses the reader because the median is sometimes also called the *average*, such as what is routinely used in reporting house prices. The reader must be careful about which one of these statistics is actually being referred to.

The arithmetic mean as defined in Equation 3 is not always a good measure of the central location of the sample in some applications. An example is when the data bear considerable variability that has nothing to do with quality control in data collection. Instead, it is inherent in the random process that gives rise to the data, such as the concentration of environmental chemicals in the air. Within a given day at a given location, their concentration could vary in magnitude by multiples. Another example is the growth of bacteria on artificial media. The number of bacteria growing on the media at a given time may be influenced by the number of bacteria on the media at an earlier time, by the amount of media available for growth, by the media type, by the different antibiotics incorporated in the media, by the micro growing environment, and so on. The growth of the bacteria proceeds, not in a linear pattern, but in a multiplicative way. The central tendency of these types of data is best described according to their product, but not their sum. The *geometric mean*, but not the arithmetic mean, would thus be closer to the center of the data values. The geometric mean ($\bar{x}_G$) of a sample of n observations, $x_1, x_2, \dots, x_n$, is defined as the n th root of the product of the n values:

$$\bar{x}_G = \sqrt[n]{x_1 x_2 \dots x_n} = \left(\prod_{i=1}^n x_i \right)^{1/n}. \quad (7)$$

Analogous to the summation representation in Equation 3, the notation $\prod_{i=1}^n$ is a succinct representation of the multiplication of all values of the sample set from the first to the n th observation. Therefore, all values from the first to the last observation are included in the product.

Comparing Equation 7 with Equation 3, one can see that the difference is that the geometric mean is obtained by multiplying the observations in the sample first and then taking the n th root of their product. In

contrast, the arithmetic mean is calculated by adding up the observations first and then dividing their sum by the number of observations in the sample. Because of the multiplying and the taking-the- n th-root operations, the geometric mean can be applied only to data of positive values, not to data of negative or zero values.

When the sample size n is large, the product of the values of the observations could be very large, and taking the n th root of the product could be difficult, even with modern computers. One way to resolve these difficulties is to transform the value of all observations into a logarithm scale. The multiplication process then becomes a summation process, and the operation of taking the n th root of the product is replaced by the division of n from the logarithm sum. The geometric mean is then obtained by applying an antilogarithm operation to the result.

For example, suppose that n observations, $x_1, x_2, \dots, x_n$, are taken from a random variable. The mean of the logarithmic product of the n values ($\bar{x}_{\log}$) in the sample is

$$\bar{x}_{\log} = \frac{1}{n} \log(x_1 x_2 \dots x_n) = \frac{1}{n} \sum_{i=1}^n \log(x_i), \quad (8)$$

and the geometric mean is then

$$\bar{x}_G = \text{anti} \log(\bar{x}_{\log}). \quad (9)$$

Here, the base of the logarithm scale can be either $e (= 2.718281828)$, the base for natural logarithm) or 10. Most often, 10 is used as the base.

MEAN COMPARISONS

The term *mean comparisons* refers to the comparison of the average of one or more continuous variables over one or more categorical variables. It is a general term that can refer to a large number of different research questions and study designs. For example, one can compare the mean from one sample of data to a hypothetical population value, compare the means on a single variable from multiple independent groups, or compare the means for a single variable for one sample over multiple measurement occasions. In addition, more complex research designs can employ multiple continuous dependent variables simultaneously, as well as a combination of multiple groups and multiple measurement occasions. Overall, mean comparisons are of central interest in any experimental design and many correlational designs when there are existing categorical variables (e.g., gender).

Two primary questions must be asked in any mean comparison: Are the means statistically different, and how big are the differences? The former question can be answered with a statistical test of the difference in means. The latter is answered with a standardized measure of effect size. Together, these more accurately characterize the nature of mean differences.

Statistical Differences

Testing for statistical differences attempts to answer the question of whether the observed differences, however large or small, are due to some real effect or simply random sampling error. Depending on the nature of the data and the specific research question at hand, different statistical tests must be employed to properly answer the question of whether there are statistical differences in the means.

z Test

The *z* test is employed when a researcher wants to answer the question, Is the mean of this sample statistically different from the mean of the population? Here, the researcher would have mean and standard deviation information for the population of interest on a particular continuous variable and data from a single sample on the same variable. The observed mean and standard deviation from the sample would then be compared with the population mean and standard deviation. For example, suppose an organization, as part of its annual survey process, had collected job satisfaction information from all its employees. The organization then wishes to conduct a follow-up study

relating to job satisfaction with some of its employees and wishes to make sure the sample drawn is representative of the company. Here, the sample mean and standard deviation on the job satisfaction variable would be compared with the mean and standard deviation for the company as a whole and tested with a *z* test. This test, however, has limited applications in most research settings, for the simple fact that information for the population is rarely available. When population information is unavailable, different statistical tests must be used.

t Test

Unlike the *z* test, the *t* test is a widely used and applicable statistical test. In general, the *t* test is used to compare two groups on a single continuous dependent variable. Generally, this statistical test answers the question, Is the mean of this sample statistically different from the mean of this other sample? By removing the assumption that there is population information available, the *t* test becomes a much more flexible statistical technique. The *t* test can be used with experimental studies to compare two experimental conditions, with correlational studies to compare existing dichotomous groups (e.g., gender), and with longitudinal studies to compare the same sample over two measurement occasions. An important limiting factor of the *t* test is that it can compare only two groups at a time; investigations of mean differences in more complex research designs require a more flexible analytic technique.

Analysis of Variance

Analysis of variance (ANOVA) is even more flexible than the *t* test in that it can compare multiple groups simultaneously. Because it is derived from the same statistical model as the *t* test (i.e., the *general linear model*), ANOVA answers questions similar to those answered by the *t* test. In fact, when comparisons are between two groups, the *t* test and ANOVA will yield the exact same conclusions, with the test statistics related by the following formula: $F = t^2$. A significant result from an ANOVA will answer whether at least one group (or condition) is statistically different from at least one other group (or condition) on the continuous dependent variable. If a significant result is found when there are three or more groups or conditions, post hoc tests must be conducted to determine exactly where the significant differences lie.

ANOVA is also the appropriate statistical test to use to compare means when there are multiple categorical independent variables that need to be tested simultaneously. These tests are typically called *n*-way ANOVAs,

where the n is the number of independent variables. Here, means among all the conditions are compared. This type of analysis can answer questions of whether there are significant effects for any of the independent variables individually, as well as whether there are any combined interactive effects with two or more of the independent variables. Again, significant results do not reveal the nature of the relationships; post hoc tests must be conducted to determine how the variables relate.

Multivariate ANOVA

Multivariate ANOVA (MANOVA) is a multivariate extension of ANOVA. Like ANOVA, MANOVA can compare the means of two or more groups simultaneously; also, an n -way MANOVA, like its n -way ANOVA counterpart, can compare the means for multiple independent variables at the same time. The key difference between these two types of analyses is that MANOVA can compare means on multiple continuous dependent variables at the same time, whereas ANOVA can compare means only for a single continuous dependent variable. As such, MANOVA answers the question of whether there are differences between any two groups on any of the dependent variables examined. Effectively, this analysis examines only the question of whether something, on any of the dependent variables, is different between any of the groups examined. As with most of the other analyses, a significant result here will require extensive post hoc testing to determine the precise nature of the differences.

Regression

Mean differences can also be assessed via multiple regression, although this approach is less common. Regression techniques can assess mean differences on a single continuous dependent variable between any number of independent variables with any number of categories per independent variable. When there is a single independent variable with two categories, the statistical conclusions from entering this variable in a regression will exactly equal those from a t test; interpreting the sign of the regression weight will determine the nature of the mean differences. When there is a single independent variable with three or more categories, this variable must first be transformed into $K - 1$ “dummy” variables, where K is the number of categories. Each of these dummy variables is then entered into the regression simultaneously, and the overall statistical conclusions from this model will exactly equal those of ANOVA; however, interpreting magnitude and significance of the regression weights from the regression

model will describe the nature of the mean differences, rendering post hoc tests unnecessary. Similarly, creating dummy variables with appropriate multiplicative terms can exactly model the results from an n -way ANOVA. Two key points regarding the multiple regression approach are that the statistical results from the regression analysis will always equal the results from the t test or ANOVA (because all are derived from the general linear model) and that post hoc tests are generally unnecessary because regression weights provide a way to interpret the nature of the mean differences.

Effect Sizes

Documenting the magnitude of mean differences is of even greater importance than testing whether two means differ significantly. Psychological theory is advanced further by examining how big mean differences are than by simply noting that two groups (or more) are different. Additionally, practitioners need to know the magnitude of group differences on variables of interest in order to make informed decisions about the use of those variables. Also, psychological journals are increasingly requiring the reporting of effect sizes as a condition of acceptance for publication. As such, appropriate effect sizes to quantify mean differences need to be examined. Generally, two types of effect size measures are commonly used to compare means: mean differences and correlational measures.

Mean Differences

Mean difference effect size measures are designed specifically to compare two means at a time. As such, they are very amenable to providing an effect size measure when one is comparing two groups via a z test or a t test. Mean difference effect sizes can also be used when one is comparing means with an ANOVA, but each condition needs to be compared with a control group or focal group. Because the coding for a categorical variable is arbitrary, the sign of the mean difference effect size measure is also arbitrary; in order for effect sizes to be interpretable, the way in which groups are specified must be very clear. Three common effect size measures are the simple mean difference, the standardized mean difference, and the standardized mean difference designed for experimental studies.

Simple Mean Difference

The simplest way to quantify the magnitude of differences between groups on a single continuous dependent variable is to compute a simple mean difference, $M_1 - M_2$, where M_1 and M_2 are the means for Groups

1 and 2, respectively. Despite its simplicity, this measure has several shortcomings. The most important limitation is that the simple mean difference is scale and metric dependent, meaning that simple mean differences cannot be directly compared on different scales, or even on the same scale if the scale has been scored differently. As such, simple mean differences are best used when there is a well-established scale whose metric does not change. For example, simple mean differences can be used to compare groups on the SAT (a standardized test for college admissions) because it is a well-established test whose scoring does not change from year to year; however, simple mean differences on the SAT cannot be compared with simple differences on the ACT, because these two tests are not scored on the same scale.

Standardized Mean Difference

The standardized mean difference, also known as Cohen's d , addresses the problem of scale or metric dependence by first standardizing the means to a common metric (i.e., a standard deviation metric, where the SD equals 1.0). The equation to compute the standardized mean difference is

$$d = \frac{M_1 - M_2}{\sqrt{\frac{N_1 (SD_1)^2 + N_2 (SD_2)^2}{N_1 + N_2}}}, \quad (1)$$

where N is the sample size, SD is the standard deviation, and other terms are defined as before. Examination of this equation reveals that the numerator is exactly equal to the simple mean difference; it is the denominator that standardizes the mean difference by dividing by the pooled within-group standard deviation. Generally, this measure of effect size is preferred because it can be compared directly across studies and aggregated in a meta-analysis. Also, unlike some other measures of mean differences, it is generally insensitive to differences in sample sizes between groups. There are several slight variants to Equation 1 to address some statistical issues in various experimental and correlational settings, but each is very closely related to Equation 1.

Another advantage of the standardized mean difference is that, because it is on a standardized metric, some rough guidelines for interpretation of the numbers can be provided. As a general rule, standardized mean differences (i.e., d values) of $d = 0.20$ are considered small, $d = 0.50$ are medium, and $d = 0.80$ are considered to be large. Of course, the meaning of the mean differences must be interpreted from within the research context, but these guidelines provide a rough metric with which to evaluate the magnitude of mean differences obtained via Equation 1.

Standardized Mean Difference for Experiments

In experimental studies, it is often the case that the experimental manipulation will shift the mean of the experimental group high enough to run into the top of the scale (i.e., create a ceiling effect); this event decreases the variability of the experimental group. As such, using a pooled variance will actually underestimate the expected variance and overestimate the expected effect size. In this case, researchers often use an alternative measure of the standardized mean difference,

$$d = \frac{M_{\text{Exp}} - M_{\text{Con}}}{SD_{\text{Con}}}, \quad (2)$$

where the Con and Exp subscripts denote the control and experimental subgroups, respectively. This measure of effect size can be interpreted with the same metric and same general guidelines as the standardized mean difference from Equation 1.

Correlational Effect Sizes

Correlational-type effect sizes are themselves reported on two separate metrics. The first is on the same metric as the correlation, and the second is on the variance-accounted-for metric (i.e., the correlation-squared metric, or R^2). They can be converted from one to the other by a simple square or square-root transformation. These types of effect sizes answer questions about the magnitude of the relationship between group membership and the dependent variable (in the case of correlational effect sizes) or the percentage of variance accounted for in the dependent variable by group membership. Most of these effect sizes are insensitive to the coding of the group membership variable. The three main types of effect sizes are the point-biserial correlation, the eta (or eta-squared) coefficient, and multiple R (or R^2).

Point-Biserial Correlation

Of the effect sizes mentioned here, the point-biserial correlation is the only correlational effect size whose sign is dependent on the coding of the categorical variable. It is also the only measure presented here that requires that there be only two groups in the categorical variable. The equation to compute the point-biserial correlation is

$$r_{pb} = \frac{M_1 - M_2}{SD_{\text{Tot}}} \sqrt{\frac{n_1 n_2}{N(N-1)}}, \quad (3)$$

where SD_{Tot} is the total standard deviation across all groups; n_1 and n_2 are the sample sizes for Groups 1 and

2, respectively; and N is total sample size across the two groups. Though it is a standard Pearson correlation, it does not range from zero to ± 1.00 ; the maximum absolute value is about 0.78. The point-biserial correlation is also sensitive to the proportion of people in each group; if the proportion of people in each group differs substantially from 50%, the maximum value drops even further away from 1.00.

Eta

Although the eta coefficient can be interpreted as a correlation, it is not a form of a Pearson correlation. While the correlation is a measure of the linear relationship between variables, the eta actually measures any relationship between the categorical independent variable and the continuous dependent variable. Eta-squared is the square of the eta coefficient and is the ratio of the between-group variance to the total variance. The eta (and eta-squared) can be computed with any number of independent variables and any number of categories in each of those categorical variables. The eta tells the magnitude of the relationship between the categorical variable(s) and the dependent variable but does not describe it; post hoc examinations must be undertaken to understand the nature of the relationship. The eta-squared coefficient tells the proportion of variance that can be accounted for by group membership.

Multiple R

The multiple R or R^2 is the effect size derived from multiple regression techniques. Like a correlation or the eta coefficient, the multiple R tells the magnitude of the relationship between the set of categorical independent variables and the continuous dependent variable. Also similarly, the R^2 is the proportion of variance in the dependent variable accounted for by the set of categorical independent variables. The magnitude for the multiple R (and R^2) will be equal to the eta (and eta²) for the full ANOVA model; however, substantial post hoc tests are unnecessary in a multiple regression framework, because careful interpretation of the regression weights can describe the nature of the mean differences.

Additional Issues

As research in the social sciences increases at an exponential rate, cumulating research findings across studies becomes increasingly important. In this context, knowing whether means are statistically different becomes less important, and documenting the magnitude of the difference between means becomes more

important. As such, the reporting of effect sizes is imperative to allow proper accumulation across studies. Unfortunately, current data accumulation (i.e., meta-analytic) methods require that a single continuous dependent variable be compared on a single dichotomous independent variable. Fortunately, although multiple estimates of these effect sizes exist, they can readily be converted to one another. In addition, many of the statistical tests can be converted to an appropriate effect size measure.

Converting between a point-biserial correlation and a standardized mean difference is relatively easy if one of them is already available. For example, the formula for the conversion of a point-biserial correlation to a standardized mean difference is

$$d = \frac{r_{pb}}{\sqrt{p_1 p_2 (1 - r_{pb}^2)}}, \quad (4)$$

where d is the standardized mean difference, r_{pb} is the point-biserial correlation, and p_1 and p_2 are the proportions in Groups 1 and 2, respectively. The reverse of this formula, for the conversion of a standardized mean difference to a point-biserial correlation, is

$$r_{pb} = \frac{d}{\sqrt{d^2 + \frac{1}{p_1 p_2}}}, \quad (5)$$

where terms are defined as before. If means, standard deviations, and sample sizes are available for each of the groups, then these effect sizes can be computed with Equations 1 through 3. Eta coefficients and multiple R s cannot be converted readily to a point-biserial correlation or a standardized mean difference unless there is a single dichotomous variable; then these coefficients equal the point-biserial correlation.

Most statistical tests are not amenable to ready conversion to one of these effect sizes; n -way ANOVAs, MANOVAs, regressions with more than one categorical variable, and regressions and ANOVAs with a single categorical variable with three or more categories do not convert to either the point-biserial correlation or the standardized mean difference. However, the F statistic from an ANOVA with two categorical variables is exactly equal to the value of the t statistic via the relationship $F = t^2$. To convert from a t statistic to a point-biserial correlation, the following equation must be used:

$$r_{pb} = \sqrt{\frac{t^2}{t^2 + df}}, \quad (6)$$

where t is the value of the t test and df is the degrees of freedom for the t test. The point-biserial correlation

can then be converted to a standardized mean difference if necessary.

MEASUREMENT INVARIANCE

Measurement invariance (also *measurement equivalence*) is given when test items measure the same latent construct for different groups of individuals or at different points in time. Latent constructs, such as attitudes or competencies, are not directly observable and are thus assessed through indicators like test items of a questionnaire. Assessing measurement invariance means to test whether indicators are interpreted in a similar manner by different individuals or by the same individuals at different occasions. If individuals show systematic differences in how they interpret the indicators (i.e., if the construct is measurement *noninvariant*), the test scores of the different groups do not reflect the same underlying construct. Consequently, the instrument is inappropriate for research purposes, as latent mean scores cannot be compared between the groups. Intelligence tests, for instance, must be tested for

measurement invariance, for example, to determine whether they can be applied to students with limited knowledge of the test language. Otherwise, students with low language proficiency would score significantly lower than students with language fluency, but not on account of their intelligence. This could lead to misdiagnoses (e.g., intellectual disability) or ill-fitting school choice decisions with profound consequences for the individual's academic career.

There are several methods for testing measurement invariance; approaches based on exploratory factor analysis (EFA) were generally replaced by methods applying confirmatory factor analysis (CFA) and differential item functioning (DIF). In this entry, following a more in-depth overview of measurement invariance, an example is given to illustrate the different steps to establish different levels of measurement invariance and the corresponding fit indices to determine measurement equivalence.

Introduction to Measurement Invariance

Since the beginning of the 21st century, the issue of measurement invariance has become increasingly important in various research disciplines that examine latent traits of individuals by means of inference statistics. Apart from differences between groups (e.g., caused by cultural, contextual, or biological variations), measurement invariance is also tested for different data points (e.g., before and after an intervention).

Suppose the prevalence of general anxiety disorder (GAD) is assessed across a population composed of different age groups using questionnaire items asking whether respondents feel constantly nervous, are easily annoyed, and have trouble sleeping. Researchers may find GAD to be prevalent among the elderly (aged 70+) owing to high item scores on sleeping problems. Another cause of their subjective sleeping problems, however, may be rooted in their reduced physiological need for sleep at the age of 70+. The individuals might, nevertheless, indicate they have sleeping problems, for example, because they are influenced by societal norms that imply night sleep of under five hours is problematic. CFA and DIF will alert researchers to the possibility that trouble with sleeping is not an indicator of GAD among certain age groups, even without prior knowledge about age-related sleeping patterns.

With regard to the given example, GAD can be regarded as a factor (i.e., a latent construct or trait that is not directly observable but measured through various indicators), in this case, questionnaire items assessing aspects of individual behavior and neurological processing. It is assumed that the unobservable level of

GAD will determine how individuals respond to each item. Conversely, these items contribute in various degrees to the explanation of the latent factor “GAD” (i.e., they show different factor loadings—factor loadings can be thought of as regression coefficients obtained by regressing the assumed factor on the pertaining indicators). For measurement invariance, it is examined whether the underlying latent structure of the construct is the same across groups (e.g., if the same items load on the same factor and with equal strength). Crucially, differences in the level of the trait are not the determining criterion for measurement invariance (e.g., high or low levels of intelligence or GAD), but that the various test items show the same relationship to the latent construct in all groups (i.e., they have the same psychometric properties).

DIF is a general term for different procedures that, similar to CFA, aim to identify supposed indicators of a latent construct that might measure different constructs across different groups, for example, the Mantel–Haenszel approach, item response theory, logistic regressions, or other nonparametric approaches (i.e., estimates are not confounded by sample characteristics).

Testing Measurement Invariance

While EFA helps researchers to *explore* the latent structure of a construct across different groups of individuals, CFA and DIF allow researchers to statistically *test* whether measures are invariant across groups.

CFA

Specifically, CFA and multigroup CFA (MG-CFA) test if a theoretically assumed factor structure—the factor model—fits the data and can be replicated with each group separately. Depending on how many specific assumptions are added to the factor model (i.e., how many constraints are introduced), different levels of measurement invariance can be distinguished ranging from weak (configural and metric invariance) to strong (scalar invariance) and strict invariance (residual invariance).

Testing measurement invariance with CFA is a multistep process:

(1) At first, the theoretically assumed factor model is fitted to each group separately. This entails testing if all items assumed to measure GAD load on the latent factor. Factor loadings (and factor correlations) should be high and positive/negative according to theoretical expectations. Beyond these item- and factor-specific coefficients, test statistics assess to what degree an assumed overall factor

model is supported by the data. **Absolute fit indices** (e.g., χ^2 ; Root Mean Square Error of Approximation, RMSEA; Standardized Root Mean Square Residual, SRMR; [Adjusted] Goodness of Fit Index, GFI/AGFI) test how well the assumed factor model fits the data in comparison to an unrestrained model that, by definition, has the highest data fit because it replicates the actual data structure and not the expected factor structure that requires constraints. **Incremental fit indices** (e.g., [Parsimony] Comparative Fit Index, CFI, PCFI; Tucker-Lewis fit index, TFI) assess how much better the assumed factor model fits the data compared to the baseline model that, by definition, has the worst data fit because it assumes no statistical interdependencies between indicators. Each fit index represents a somewhat different approach to assess absolute/incremental model fit, and their availability may vary depending on characteristics of the data and statistical software used to analyze it. The literature differs with respect to recommendations in how to interpret each fit index, but a general guideline is:

<i>Fit Index</i>	<i>Range</i>	<i>Higher (Adequate) Model Fit Indicated by</i>
χ^2 test: <i>p</i> value	[0;1]	Nonsignificant <i>p</i> value (<i>p</i> ≥ .2)
RMSEA	[0;1]	Lower values (<.06)
SRMR	[0;1]	Lower values (<.10)
GFI/AGFI	[0;1]	Higher values
CFI/PCFI/TFI	[0;1]	Higher values (≥.95)

(2) In a second step, the (revised) factor model is fitted to each group separately and factor loadings as well as fit indices are assessed for each group model. If researchers find that the same items load on the same factor in each group and that fit indices signal adequate model fit for each group model (also compared to the reference model of Step 1), **configural invariance** is established, which is a necessary but weak test of measurement invariance. Regarding the example of GAD, this step may reveal that the indicator for sleeping problems does not load on the factor “GAD” equally strong among older individuals compared to younger individuals (i.e., among older respondents, the prevalence of sleep problems is not as strongly connected to other indicators of GAD).

(3) For greater certainty, MG-CFA is conducted, which allows researchers to introduce constraints to the factor model to test whether the factor loadings of any given item are equal between different groups. Researchers specify that the factor model will be fitted to the data under the assumption that the factor loading of each item is equal between groups (which does not prescribe the

actual value of the factor loadings). If the assumption is untenable, all estimations will be a poor reproduction of the data (i.e., model fit as indicated by fit indices will be inadequate). If the model fit is not worse than the reference model that was found to be configural invariant during Step 2, **weak factorial invariance applies** (also called *metric invariance*). With regard to GAD among younger and older individuals, this step might reveal that even given differing factor loadings of the indicator for sleep problems between the groups, overall model fit of the MG-CFA is still adequate.

(4) Subsequently, researchers may further test if item intercepts are equal across groups by introducing the necessary constraints and retesting the factor model using MG-CFA. Intercepts are the value of indicators expected when the factor score is fixed at 0 (e.g., how individuals would answer the questionnaire items if they are completely unaffected by GAD). By comparing the model fit to the fit of the weak factorial invariance model, researchers can assess if **strong factorial invariance** (also *scalar invariance*) between groups holds. If intercepts are not equal across groups for any given item, groups show different item scores independent of the underlying latent construct. In the case of GAD, it is assumed that older individuals report higher sleep problems because of their age, not because of higher GAD—this is an example where the assumption of strong factorial invariance is likely untenable.

If strong factorial invariance is established, it can be assumed that differences in GAD scores across groups are attributable to differences in their GAD level, and all items are interpreted in the same manner across groups. In case few items induce problems in establishing measurement invariance, researchers have to decide whether the pertaining items should be excluded or replaced in composing the final scale or whether partial strong factorial invariance is sufficient in the context of the application of the scale (e.g., assessing GAD among younger individuals exclusively).

(5) Although seldom applied, researchers may want to test whether item residuals of a given item are equal between groups (i.e., if **residual invariance holds**). That means that the variance in answers of individuals to the questionnaire item in one group can be as effectively explained (or predicted) with differences in the latent construct compared to all other groups.

DIF

DIF describes the relationship between a latent construct and indicators as probabilistic: Higher latent construct scores (e.g., higher levels of GAD) increase

the probability of individuals to give certain responses to indicators (e.g., affirming the item “I constantly feel nervous”). Beyond a certain latent construct score, the probability to endorse an item becomes greater than 50% (e.g., individuals with that level of underlying GAD affirm constant nervousness more often than not); this so-called inflection point defines the difficulty of an item (Parameter b). Items further vary in their ability to discriminate between individuals: Regarding some items, a large increase in latent construct scores might correspond to small increases in the probability to affirm the item—such items fail to discriminate efficiently between individuals and have a low value for discrimination (Parameter a). High values indicate that a small increase in latent scores corresponds to a large increase in the probability to affirm an item.

If an item displays a different difficulty (Parameter b) between groups while keeping discrimination (Parameter a) constant, measurement invariance is questionable. It is helpful to inspect difficulties of items visually by plotting the probability to endorse an item against latent construct scores (item characteristic curves). A version of the Student's *t* test is used to test whether the displayed difference in difficulty is significant. The Wald statistic or likelihood-ratio tests can be conducted to test for statistically meaningful differences in both the difficulty and discrimination of an item, which is often warranted. If the assumption of measurement invariance is rejected, the pertaining item displays a differential item function. In that case, researchers have to consider how to proceed with the construction of the scale (e.g., excluding or replacing problematic items).

MEDIAN

The median is one of the location parameters in probability theory and statistics. (The others are the mean and the mode.) For a real valued random variable X with a cumulative distribution function F , the median of X is the unique number that satisfies $F(-m) \leq \frac{1}{2} \leq F(m)$. In other words, the median is the number that separates the upper half from the lower half of a population or a sample. If a random variable is continuous and has a probability density function, half of the area under the probability density function curve would be to the left of m and the other half to the right of m . For this reason, the median is also called the 50th percentile (the i th percentile is the value such that $i\%$ of the observations are below it). In a box plot (also called box-and-whisker plot), the median is the central line between the lower and the higher hinge of the box. The location of this central line suggests the central tendency of the underlying data.

The population median, like the population mean, is generally unknown. It must be inferred from the sample median, just like the use of the sample mean for inferring the population mean. In circumstances in which a sample can be fitted with a known probability model, the population median may be obtained directly from the model parameters. For instance, a random variable that follows an exponential distribution with a scale parameter β (a scale parameter is the one that stretches or shrinks a distribution), the median is $\beta \ln 2$ (where $\ln$ means natural logarithm, which has a base $e = 2.718281828$). If it follows a normal distribution with a location parameter μ and a scale parameter σ , the median is μ . For a random variable following a Weibull distribution with a location parameter μ , a scale parameter α , and a shape parameter γ (a shape parameter is the one that changes the shape of a distribution), the median is $\mu + \alpha(\ln 2)^{1/\gamma}$. However, not all distributions have a median in closed form. Their population median cannot be obtained directly from a

probability model but has to be estimated from the sample median.

Definition and Calculation

The sample median can be defined similarly, irrespective of the underlying probability distribution of a random variable. For a sample of n observations, $x_1, x_2, \dots, x_n$, taken from a random variable X , rank these observations in an ascending order from the smallest to the largest in value; the sample median, m , is defined as

$$m = \begin{cases} x_k & \text{if } n = 2k + 1 \\ (x_k + x_{k+1}) / 2 & \text{if } n = 2k \end{cases} \quad (1)$$

That is, the sample median is the value of the middle observation of the ordered statistics if the number of observations is odd or the average of the value of the two central observations if the number of observations is even. This is the most widely used definition of the sample median.

According to Equation 1, the sample median is obtained from order statistics. No arithmetical summation is involved, in contrast to the operation of obtaining the sample mean. The sample median can therefore be used on data in ordinal, interval, and ratio scale, whereas the sample mean is best used on data in interval and ratio scale because it requires first the summation of all values in a sample.

The sample median as defined in Equation 1 is difficult to use when a population consists of all integers and a sample is taken with an even number of observations. Because the median should also be an integer, two medians could result. One may be called the lower median and the other, the upper median. To avoid calling two medians of a single sample, an alternative is simply to call the upper median the sample median, ignoring the lower one.

If the sample data are grouped into classes, the value of the sample median cannot be obtained according to Equation 1 as the individual values of the sample are no longer available. Under such a circumstance, the median is calculated for the particular class that contains the median. Two different approaches may be taken to achieve the same result. One approach starts with the frequency and cumulative frequency (see Ott and Mendenhall, 1994):

$$m = L + \frac{w}{f_m} \left(\frac{n}{2} - cf_b \right), \quad (2a)$$

where m = the median, L = lower limit of the class that contains the median, n = total number of observations in the sample, cf_b = cumulative frequency for all

classes before the class that contains the median, f_m = frequency for the class that contains the median, and w = interval width of the classes.

The other approach starts with the percentage and cumulative percentage:

$$m = L + \frac{w}{P_m}(50 - cP_b), \quad (2b)$$

where 50 = the 50th percentile, cP_b = cumulative percentage for all classes before the class that contains the median, and P_m = percentage of the class that contains the median. Both L and w are defined as in Equation 2a. A more detailed description of this approach can be found in *Arguing With Numbers* by Paul Gingrich.

This second approach is essentially a special case of the approach used to interpolate the distance to a given percentile in grouped data. To do so, one needs only to replace the 50 in Equation 2b with a percentile of interest. The percentile within an interval of interest can then be interpolated from the lower percentile bound of the interval width.

To show the usage of Equations 2a and 2b, consider the scores of 50 participants in a hypothetical contest, which are assigned into five classes with the class interval width = 20 (see Table 1). A glance at the cumulative percentage in the right-most column of the table suggests that the median falls in the 61-to-80 class because it contains the 50th percentile of the sample population. According to Equation 2a, therefore, $L = 61$, $n = 50$, $cf_b = 13$, $f_m = 20$, and $w = 20$. The interpolated value for the median then is

$$m = 61 + \frac{20 \times (50 / 2 - 13)}{20} = 73.$$

Using Equation 2b, we have $cP_b = 26$, $P_m = 40$, both $L = 61$, and $w = 20$, as before. The interpolated value for the median of the 50 scores, then, is

$$m = 61 + \frac{20 \times (50 - 26)}{40} = 73.$$

Equations 2a and 2b are equally applicable to ordinal data. For instance, in a survey on the quality of customer services, the answers to the customer satisfaction question may be scored as *dissatisfactory*, *fairly satisfactory*, *satisfactory*, and *strongly satisfactory*. Assign a value of 1, 2, 3, or 4 (or any other ordered integers) to represent each of these classes from *dissatisfactory* to *strongly satisfactory* and summarize the number of responses corresponding to each of these classes in a table similar to the one above. One can then apply either Equation 2a or Equation 2b to find the class that contains the median of the responses.

Determining Which Central Tendency Measure to Use

As pointed out at the beginning, the mean, the median, and the mode are all location parameters that measure the central tendency of a sample. Which one of them should be used for reporting a scientific study? The answer to this question depends on the characteristics of the data, or more specifically, on the *skewness* (i.e., the asymmetry of distribution) of the data. A distribution is said to be skewed if one of its two tails is longer than the other. In statistics literature, the mean (μ), median (m), and mode (M) inequality are well known for both continuous and discrete unimodal distributions. The three statistics occur either in the order of $M \leq m \leq \mu$ or in a reverse order of $M \geq m \geq \mu$, depending on whether the random variable is positively or negatively skewed.

For random variables that follow a symmetric distribution such as the normal distribution, the sample mean, median, and mode are equal and can all be used to describe the sample central tendency. Despite this, the median, as well as the mode, of a normal distribution is

Table 1 Grouped Data for 50 Hypothetical Test Scores

Class	Number of Observations	Frequency		
		Cumulative Number of Observations	%	Cumulative %
0–20	2	2	4	4
21–40	5	7	10	14
41–60	6	13	12	26
61–80	20	33	40	66
81–100	17	50	34	100
	50		100	

not used as frequently as the mean. This is because the variability (V) associated with the sample mean is much smaller than the V associated with the sample median ($V[m] = [1.2533]^2 V[\mu]$). If a random variable follows a skewed (i.e., nonsymmetrical) distribution, the sample mean, median, and mode are not equal. The median differs substantially from both the arithmetic mean and the mode and is a better measure of the central tendency of a random sample because the median is the minimizer of the mean absolute deviation in a sample. Take a sample set $\{2, 2, 3, 3, 3, 4, 15\}$ as an example. The median is 3 (so is the mode), which is a far better measure of the centrality of the data set than the arithmetic mean of 4.57. The latter is largely influenced by the last extreme value, 15, and does not adequately describe the central tendency of the data set. From this simple illustration, it can be concluded that the sample median should be favored over the arithmetic sample mean in describing the centrality whenever the distribution of a random variable is skewed. Examples of such skewed data can be found frequently in economic, sociological, education, and health studies. A few examples are the salary of employees of a large corporation, the net income of households in a city, the house price in a country, and the survival time of cancer patients. A few high-income earners, or a few high-end properties, or a few longer survivors could skew their respective sample disproportionately. Use of the sample mean or mode to represent the data centrality would be inappropriate.

The median is sometimes called the *average*. This term may be confused with the mean for some people who are not familiar with a specific subject in which this interchangeable usage is frequent. In scientific reporting, this interchangeable use is better avoided.

Advantages

Compared with the sample mean, the sample median has two clear advantages in measuring the central tendency of a sample. The first advantage is that the median can be used for all data measured in ordinal, interval, and ratio scale because it does not involve the mathematic operation of summation, whereas the mean is best used for data measured in interval and ratio scale. The second advantage is that the median gives a measure of central tendency that is more robust than the mean if outlier values are present in the data set because it is not affected by whether the distribution of a random variable is skewed. In fact, the median, not the mean, is a preferred parameter in describing the central tendency of such random variables when their distribution is skewed. Therefore, whether to use the sample median as a central tendency measure depends on the data type. The median is used if a random

variable is measured in ordinal scale or if a random variable produces extreme values in a set. In contrast, the mean is a better measure of the sample central tendency if a random variable is continuous and is measured in interval or ratio scale, and if data arising from the random variable contain no extreme value.

When one is using the sample median, it helps to remember its four important characteristics, as pointed out by Lyman Ott and William Mendenhall:

1. The median is the central value of a data set, with half of the set above it and half below it.
2. The median is between the largest and the smallest value of the set.
3. The median is free of the influence of extreme values of the set.
4. Only one median exists for the set (except in the difficult case in which an even number of observations is taken from a population consisting of only integers).

MEMBER CHECKS

The term *member check* refers to a set of processes in which researchers *check in* with participants in a qualitative study so that participants can consider and respond to their comments in the data and/or to researchers' interpretations of the data. Member checks are often (and ideally) used in combination with other

methods to establish a study's validity, particularly a study's credibility. Member checks are important in research studies because determining whether and how participants *see themselves* and relate to the data and the researchers' interpretations (or whether and how they do not) can help to ensure the credibility and reliability of the research process including data collection, analysis, and reporting.

Member checks can also be referred to as *participant* or *respondent validation strategies*; some researchers prefer these terms because they signify a more process-oriented and relational approach rather than a one-time, transactional interaction. Regardless of the term, the goal of member checks is to help researchers determine whether and how they understand participants' experiences, perspectives, and realities.

Member checks can be technical processes, which may involve having participants verify the accuracy of statements in transcripts. Member checks can also be analytical in which participants respond to or engage with a researcher's interpretations at different stages of analysis. This entry focuses on the role of member checks in relationship to study credibility, provides an overview of the processes of member checking, and discusses some critiques of and challenges to conducting member checks.

Establishing Credibility

Conducting member checks is a method that qualitative researchers use to enhance the validity or trustworthiness of a study; specifically, member checks are often used to establish credibility, which means that the research findings are believable to research participants. Validity in qualitative research should not be thought of as simply being achievable through a checklist of items. Because validity refers to the quality and rigor of a study, researchers should engage in validity techniques systematically throughout an entire study, and member checks are an important way to engage participants at various stages of data collection and analysis. It is in this regard that member checks can inform the credibility of a study because conducting member checks means that participants have had opportunities to react to the data and/or researchers' interpretations. Member checks should be conducted with fidelity to participants and their experiences in such a way that participants' feedback and challenges are seriously considered and help inform the interpretive frames of a study.

Process Overview

Member checks can occur in a variety of ways. For example, they may take place informally during data

collection (i.e., during an interview or focus group to check for understanding) or more formally during a follow-up interview, meeting, or conversation. Member checks can involve checking in with participants to determine accuracy, engaging in sustained dialogue with participants, and/or involving participants in collaborative data analysis processes.

The processes that researchers select vary depending on the qualitative approach, study goals, research questions, and issues of participant availability and access. The process should involve sufficient time in the overall research design and time line so that researchers can actively engage with and respond to participants' critiques, interpretations, and additions. Ideally, member checks are employed at multiple points throughout a study so that they are proactively and intentionally structured into a study's research design and not tacked on at the end of a study. When done with fidelity, participant validation processes often result in additional data that can contribute to a study's ability to capture and represent complexity. These processes (e.g., follow-up interviews) should be systematically recorded and analyzed in the same ways as all other forms of data.

To be clear, member checks can be technical—moments when participants are asked to respond to the accuracy of data—or they can be analytical—times when participants may respond to analytical themes, codes, and/or findings. Member checks ideally occur continuously throughout data collection and analysis. That is why some contemporary methods scholars prefer the term *participant validation* because it better captures the processes by which qualitative researchers continuously engage with participants to help make sure they understand, to the fullest extent possible, participants' experiences and perspectives.

Critiques and Challenges

When not considered holistically, member checks have the potential to denote that there is a single truth to be determined and then confirmed, which runs contrary to the interpretivist paradigm of qualitative research, which contends that there is no single truth but rather multiple, situated realities. When participant validation processes are approached as holistic ways of engaging with and understanding participants' experiences, and not solely as a form of verification, they become a vital part of establishing validity in qualitative research.

It is important to think through potential challenges that could arise during member checks and to make sure that researchers make the most of participants' time. This involves researchers reflecting on what they hope to achieve as a result of checking in with participants. For example, if sharing transcripts, what are

participants supposed to do with the transcript (i.e., see if they still agree with what they stated? Add to points they have made? Clarify language and concepts?) and how should researchers respond to them? If discussing the researchers' interpretations, how should researchers react if the participant disagrees with their interpretations? Researchers should consider multiple ways to approach member checks, receive feedback from participants, and integrate that feedback in meaningful ways that relate to the study's data and analysis.

Member checks can help qualitative researchers conduct rigorous and valid studies by assessing and challenging the researcher's interpretations, but it is important to remember that solely conducting member checks does not mean that a study is considered valid. Engaging participants in analysis and interpretation is an important process that should, when appropriate to the research design, be used to strengthen the rigor and validity of a qualitative research study.

MEMOS

In qualitative research, memos are documents that a researcher uses to record processes and outcomes. While commonly associated with grounded theory, memos are an important tool in all forms of research, regardless of the methodology or study design

employed. This entry examines the purpose of memos in qualitative research and explains their use as a methodological tool.

Purpose of Memos

Qualitative research is built on the premise that there is no singular reality. In the qualitative domain, multiple perspectives exist that inform the understanding of a phenomenon. The coexistence of multiple realities can create ambiguity, particularly for the researcher who is unfamiliar with the principles of qualitative research. Through the process of memoing, the researcher can reflect on different perspectives and how each informs the research process. Memoing also provides for the researcher to prioritize and thereby manage the large volume of data that characterizes qualitative research. Memos serve a number of critical purposes in research; here, we categorize them as positioning the researcher, promoting rigor in the research process, and aiding the process of analysis.

Positioning the Researcher

Working with the multiple realities that characterize qualitative research requires the researcher to be aware of their own perspectives, assumptions, and implicit biases. Through the use of memoing, the researcher can continuously articulate their position in relation to the research from the outset of the study. Memos offer an opportunity for a researcher to engage in critical discussions with their own self. As a consequence, insight is developed and the potential for confounding assumptions or biases is reduced.

Promoting Rigor

Many qualitative research designs are emergent in nature, that is, decisions made in respect of the direction of research are informed by analysis as the study progresses. In a practical sense, memos provide research rigor by facilitating a recording of decision-making at various stages of the study. Memos function as an audit trail throughout the research. Rationale for decisions are captured and the subsequent research activities are tracked and mapped through memoing. Memos, therefore, provide a contemporaneous record of a research study for subsequent review as a measure of rigor.

Aiding Analysis

One of the most important functions of memos is to aid analysis. Through the use of memos, the researcher enters a dialogue with the data. In working with the often ambiguous concepts characteristic of qualitative

research, memos help the researcher to clarify their thinking. Memoing enables codes and coding processes to be unpacked and linkages between related concepts to become crystalized. As qualitative researchers aim to construct meaning from the experience of phenomena, there is a need to raise concrete data from descriptive to abstract levels. Memoing is a key strategy for achieving this outcome, particularly for novice researchers who may otherwise be uncomfortable with the conceptual leaps necessary to move from description to abstraction. This outcome is possible as memoing enables the researcher to take risks in exploring the data and experiment with ideas that may otherwise be left untested.

There is potential to become overwhelmed with the large volumes of data that are often generated in qualitative research. Using memos in the aid of analysis prevents the research from become stuck on a concept or recovering old ground, as records of decisions and their rationale are captured in memos. Memos provide a condensed account of the researcher's thinking about a particular topic that can be used to rationalize their analytical concepts and focus their future data collection and analysis.

Approaches to Memoing

Memos are produced by a researcher to facilitate various elements of the research process. Memos are an adjunct to other documents such as transcripts and field notes and may in themselves be a form of data for analysis. While memos can be used to facilitate communication within a research team, they are largely personal documents. For this reason, there will be great variation in the way in which memoing is used, the structure that memos take, and the process by which they are produced.

Types of Memos

Some researchers choose to categorize memos in different ways to distinguish their function. For example, operational memos may be used to record decisions made in respect of research design, coding memos may summarize coding processes and outcomes, and analytical memos may summarize the process of analysis. Categorization is not essential, however. Providing that memos are labeled, filed, and cross-referenced in a way that permits ease of search and retrieval by the individual researcher, any (or no) typology is appropriate.

Structure of Memos

As with other aspects of memoing, the structure of memos should be individualized to meet the style of the

researcher. Some structural principles are proposed, however, such as ensuring the memos have a title that reflects their content and are dated. Memos can span the entire duration of a study, in which case additional entries are dated when they are added, or they may capture a single, isolated concept or process.

Researchers generally find that memos change in structure over time as a study progresses. They will likely move from a formal record of activities to more personalized and critical exploration of ideas and processes. As memos are intended for use by the researcher or research team alone, this evolution of content and style is expected and conducive to progressing analytical processes.

Memoing Process

Using memos in qualitative research requires a level of commitment, particularly in the early stages. The important role that memos play in research reinforces the need to establish a method of memoing that works for the individual researcher. Making the production of memos a laborious process will see it become a chore, reducing the likelihood that this strategy for improving research processes and outcomes will become an ingrained component of research design.

Memos should be a safe place for researchers to express thoughts, feelings, opinions, and concerns. Writing should be undertaken as freely as possible; grammar, spelling, and punctuation are secondary to the need to capture insights and actions. Written memos help novice researchers get comfortable with and develop their writing style, with the content of memos often becoming the basis for research reports.

Memos may be produced using pen and paper, a word processing program, or voice recorder. There are a number of note-taking applications that enable you to create and store memos (e.g., Evernote and Microsoft OneNote). Qualitative data analysis software programs (e.g., NVivo) enable memo production and storage in the context of analysis.

META-ANALYSIS

A meta-analysis is a specific type of systematic review that includes a quantitative pooling of data. Although the term dates back to 1976, use of these techniques greatly expanded with the foundation of the Cochrane Collaboration in 1993. Meta-analyses rely on secondary or published data, thereby removing the need for further approval from an ethics committee. Meta-analyses and systematic reviews of randomized controlled trials (RCTs) are the most robust form of research design in the hierarchy of research evidence, with Cochrane systematic reviews representing the gold standard for these methodologies. However, these techniques can also be applied to observational studies.

This introduction to meta-analyses describes the process of undertaking a review of either RCTs or observational studies. Tasks outlined include registering the title and protocol with an appropriate registry such as the Cochrane Collaboration or PROSPERO and then undertaking the review based on that protocol. The use of appropriate meta-analytical techniques are described including appropriate tests to use for continuous and dichotomous variables (e.g., mean difference [MD], relative risks, or odds ratios [ORs]), and the use of fixed or random effects. Examples of bibliographic software and freeware for meta-analyses such as Review Manager (RevMan) or WINPEPI are also highlighted.

Why Do a Meta-Analysis?

By pooling the results from multiple studies, a meta-analysis increases statistical power and hence the chance of detecting a statistically significant effect, if it exists. In particular, including patients from a number of trials increases the chances of detecting an effect that may have not have otherwise been detected in a small individual trial.

Good Practice in Reporting a Meta-Analysis

There are several important issues to consider before any data analysis is performed. Crucially, these will enhance the quality of subsequent findings.

Use of the Appropriate Guidelines for Reporting a Systematic Review

Guidelines for meta-analyses have been established and accepted, and following such accepted guidelines is

a requirement for publication in many journals. For meta-analyses of RCTs, these guidelines are compiled in a statement called the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA; see Table 1). Although this statement focuses on randomized trials, it can also be used for other designs, such as service evaluation, and consists of a checklist and flow diagram. For observational studies, the appropriate recommendations are compiled in the Meta-analyses of Observational Studies in Epidemiology (MOOSE) statement. A disadvantage of these tools is that they only apply to specific aspects and types of reviews, as opposed to being global guidelines (see Table 1). As a result, a Measurement Tool to Assess Systematic Reviews has been developed to evaluate systematic reviews that include both randomized and/or nonrandomized studies (see Table 1). Finally, the National Institute of Health has produced a tool that can be applied to a broad range of systematic reviews and meta-analyses whether these are of observational or experimental studies (see Table 1). Given the range of alternatives, it is advisable to pick the option that best suits a particular meta-analysis.

Prospective Registration of a Protocol

Authors of meta-analyses typically register the review's protocol with an appropriate repository or registry. In the case of Cochrane reviews, this is a mandatory step prior to completion of the meta-analysis. For other meta-analyses, an alternative is PROSPERO (see Table 1). PROSPERO is an online repository of protocols similar to clinical trial registries or protocols in the Cochrane Library, hosted by the Centre for Reviews and Dissemination at the University of York. These are shorter than Cochrane protocols and cover the study design of interest, the condition under review, the target population, any comparison group, relevant outcomes, and any proposed intervention. The proposed search terms, methods of data extraction, and methods of assessing study quality are also required. All accepted meta-analyses are given a registration number, which is then cited in the published meta-analysis. Open science framework and some clinical trial registries also accept protocols for meta-analysis (see Table 1). Another option is researchregistry.com, which unlike the previously mentioned repositories, charges a fee for each registration.

Use of a Clearly Focused Question

The meta-analysis protocol and subsequent review typically give a clear indication of the population studied (P), the intervention or exposure (I), control group

if relevant (C), outcome (O), and study (S) design—often referred to as PICOS. The appropriate design depends on the research question. For observational studies, these might include case control and cohort designs, whereas experimental studies include controlled, quasi-experimental and RCTs. Results from randomized and nonrandomized trials should not be combined in the same individual comparison or analysis as the latter are subject to bias from known and unknown confounders that randomization is designed to minimize.

A Comprehensive Search Strategy

To ensure that all studies relevant for the meta-analysis are identified, a comprehensive search strategy is needed. Such a strategy is explicit, guided by a professional librarian, includes all relevant databases, is not limited to papers published in English, and has clear inclusion and exclusion criteria. Commonly used databases in health are the Cochrane controlled trials register, PubMed/Medline, Cinahl, Embase, and PsycINFO. International Pharmaceutical Abstracts and SPORTdiscus are more specific and thus are included in

meta-analysis related to pharmacy, physiotherapy, or human movement studies. In other fields, ProQuest Central includes 47 databases in the social sciences, arts, humanities, science and technology, whereas Education Resources Information Center and A+Education focus on education. In addition, Sociological Abstracts, Scifinder, and Social Services Abstracts cover similar areas.

Other less accessible databases include the following: the Chinese Biomedical Literature Service System, China Knowledge Resource Integrated Database, KCI-Korean Journal, Russian Science Citation Index, Scielo Citation Index, African Journals Online, and PakMediNet. These cover papers from Russia, Latin America, Spain, Portugal, the Caribbean, Africa, East Asia, and South Asia that may not be included in the usual bibliographic databases.

Finally Scopus, Web of Science, and Google Scholar have a particularly wide reach and cover most of the aforementioned fields. In all cases, a comprehensive strategy includes supplementing the database searches with hand searches of selected journals and retrieved articles, including follow-up from reference lists. Unpublished papers should also be sought so as to minimize publication bias (see section on publication bias later in this entry). Methods might include searching through clinical trial registries for any possible ongoing or unpublished articles or personal contact with experts.

Article Selection and Data Extraction

Article selection and data extraction should be done independently by at least two people to avoid selection bias. This involves three steps. The first is to see whether any studies can be excluded on the basis of title alone. Second, abstracts are reviewed and a smaller number of studies requiring review of the full-text paper are selected. Finally, data from all included studies are entered into a table that includes the number of participants, their age and gender, setting, intervention, and outcomes, as measured on standardized instruments. These steps are then described in detail in a flow diagram that gives details of how many studies were included and excluded at each stage, commonly done using a MOOSE or PRISMA checklist and diagram.

Data Extraction and Entry

Again, data extraction and entry should be performed by at least two reviewers independently of each other to minimize bias. For dichotomous variables, numerators and denominators are needed, whereas for continuous ones, the mean and standard deviation or error are needed.

Analysis

Early quantitative analyses were restricted to *vote-counting* studies that showed benefit, harm, or no difference. However, unlike meta-analysis, this method did not take account of study size or strength of the effect. By contrast, meta-analyses take both into account and therefore can both increase statistical power, as determined by the p value, and improve precision, as shown by narrower confidence intervals (CIs). These analyses are especially valuable in situations in which there are only small, or possibly underpowered, studies and can therefore establish the true effect of a risk factor or intervention when large studies may be impractical. However, meta-analyses are inappropriate when studies or outcomes are clinically diverse, when they contain a mix of comparisons, are of poor quality, or are in the presence of serious publication and reporting bias.

The ways in which an effect can be measured depend on the nature of the data. If the outcome is dichotomous (e.g., disease *versus* no disease, remission *versus* no remission), then ORs or risk ratios (RRs) are used. RRs are generally used in the meta-analyses of prospective studies, whereas ORs are used for case-controlled and cross-sectional studies. It is also possible to combine hazard ratios (HRs) from survival analyses.

Continuous variables can be either end point data or a change in scores where the baseline value is subtracted from the final score. End point and change data from the same measure (e.g., weight in kilograms), or instrument (e.g., the Short-Form 36), can both be entered into a meta-analysis of MDs. When different studies report on the same phenomenon (e.g., depression) but use different scales (e.g., the Becks Depression Inventory and Hamilton Rating Scale for Depression, both being rating scales for depression), the standardized mean difference (SMD) should be used. A common method of calculation is Cohen's d , which is the difference between the means divided by the pooled standard deviation. However, this overestimates the effect size in small studies and is not suitable when the groups differ in size. A better alternative is Hedges' g , which uses a slightly different formula to calculate the pooled variance by weighting each group's standard deviation by its sample size. This is the standard output in several meta-analytical programs such as RevMan. Unlike MDs, SMDs of end point and change data cannot be combined in the same meta-analysis.

All these are measures of relative effect, but sometimes studies report measures of absolute effects, such as the risk difference or number-needed-to-treat, which can also be incorporated into many meta-analytical programs.

In all of the aforementioned situations, there may be times when an individual study reports scores from different scales for the same outcome (e.g., a Becks Depression Inventory and a Hamilton Depression Rating Scale) presenting the reader with a choice of one of two outcome scales for inclusion in the meta-analysis. When this situation arises, it is preferable to use the outcome that is most used in the other included studies, but then to do a sensitivity analysis of the effect of using the other.

Controls can be either active, such as another proven intervention, or passive such as a wait-list or treatment as usual. Where possible, these should be entered as separate subgroups in the analysis. A decision on combining subgroups in an overall analysis or just presenting separate results for each subgroup is dependent on the similarity of the subgroups.

Some studies may combine multiple interventions *versus* one set of controls (e.g., a study comparing anti-hypertensives of different classes such as β -blockers *versus* Angiotensin-converting enzyme (ACE) inhibitors *versus* diuretics *versus* controls). If each of these comparisons is combined in a meta-analysis, the number of subjects in the control group of interest has to be divided by three (or how many times it appears in each comparison) to avoid inflating total numbers by counting the same individuals more than once. The same would apply when one intervention is compared against multiple controls (e.g., cognitive behavioral therapy *versus* two alternative forms of psychotherapy). In this situation, it is the number of subjects in the intervention group that must be adjusted.

Fixed Effects or Random Effects

There are two main techniques for summarizing results. A *fixed-effects model* assumes little study-to-study variability, whereas the *random-effects model* assumes that effects vary across studies. Fixed-effects models are more likely to find significant differences but are only appropriate when no clinical, methodological, or statistical heterogeneity is suspected. In this case, the random-effects model should always be used.

In all cases, the typical graph for displaying the results of a meta-analysis is a forest plot. This displays the 95%CI of an estimate (e.g., SMDs, ORs, RRs, or HRs), with the interval width indicating the precision of the estimate. The plot should be inspected for any outlying studies and possible reasons investigated. Explanations might include errors in data entry or that the study was inappropriate for inclusion.

Heterogeneity

A related topic to the visual inspection of outliers is the assessment of whether studies were sufficiently

similar for inclusion in a meta-analysis. Differences or heterogeneity in studies may be clinical (e.g., different types of participants, interventions, or outcomes), methodological (variations in trial design or quality), or statistical (where the observed differences are greater than expected by chance as a result of either clinical or methodological differences). In the first instance, clinical judgment can be a guide in whether trials are sufficiently similar in terms of participants, interventions, comparisons, or outcomes. Heterogeneity should also be suspected if the results on the forest plot vary greatly in their direction. There are also statistical tests for heterogeneity such as the I^2 statistic. This ranges from 0% to 100%, where 0% means there is no heterogeneity while cutoffs of above 25%, 50%, and 75% represent low, moderate, and high heterogeneity, respectively. The I^2 value is usually presented at the bottom of a feather plot and is superior to sole reliance on the Q statistic, which is often also displayed, and where a significant p value suggests heterogeneity. This is because the I^2 does not depend on the number of papers in a meta-analysis and therefore has greater power to detect heterogeneity when there are relatively few studies.

If statistical heterogeneity is present, it should be further explored through subgroup analysis (e.g., specific age groups) or excluding studies in a sensitivity analysis. Random-effects models (discussed later in this entry) can incorporate heterogeneity to some extent. A final approach is meta-regression, whereby the effects of factors such as gender and age can be investigated as independent variables (also discussed later in this entry). This technique is available in some freeware, statistical package plug-ins and commercial software, but not in RevMan.

Clustered RCTs

Clustered RCTs are a special case, as they randomize subjects at a program or unit level, not individually. However, participants in this situation may resemble each other more than by chance (e.g., general practitioner clinics in affluent *versus* socially deprived neighborhoods), thereby overestimating the potential benefits. As a result, the effect size of each study should be adjusted by using the intraclass correlation, a number from 0 to 0.99 derived from external databases.

Software

Of the available software, RevMan is the most commonly used freeware for meta-analyses. It is a statistical package for Cochrane Collaboration systematic reviews and is downloadable free from the

Cochrane Collaboration, along with an instruction manual (see Table 1). There is also a web-based version, which is available only to Cochrane systematic review authors. One useful feature of RevMan is the facility to import references directly as text files from databases such as Medline or from bibliographic software such as Endnote. It can support pairwise analyses of continuous and dichotomous raw data, as well as directly entered effect size using generic inverse variance. This can be particularly useful in observational studies where results have been adjusted for confounders (see the Advanced Techniques section later in this entry). Other freely available packages include WINPEPI, OpenMeta[Analyst], and Meta-Essentials (see Table 1 for the website for meta-analysis freeware). There are also plug-ins for Microsoft Excel spreadsheets such as MetaEasy and MetaXL as well as macros for common statistical packages (see Table 1). For instance, the statistical program R has meta-analysis packages, such as *metafor*. These applications include features that are not available in RevMan such as cumulative and meta-regression, where the influence on outcome of covariates such as age or gender can be explored, as well as network meta-analysis (see Advanced Techniques section).

There are also commercial software packages, such as Comprehensive Meta-Analysis, that offer an even wider range of options including the meta-analysis of before-and-after studies and the ability to combine dichotomous and continuous outcomes in the same analysis. A cost-free alternative is to use online calculators that derive effect sizes from other types of effect estimates and then enter these into freeware programs (see Table 1). This permits a range of functions that is nearly as wide as that available through commercial packages, especially for meta-analyses of a small number of studies.

Quality Assessment

Quality assessment is an important part of any meta-analysis as the robustness of results is dependent on the quality of the underlying studies. As with study selection and data extraction, this should be assessed independently by more than one person to minimize bias. In the case of RCTs, the Cochrane risk of bias tool is commonly used (see Table 1). This covers area such as an adequate generation of allocation sequence, concealment of allocation to intervention groups, blinding of participants or investigators, attrition bias and selective outcome reporting. Each item is scored as being of high, low, or unclear risk of bias. In the case of case control and cohort studies, an alternative is the Newcastle–Ottawa tool (see Table 1). There are slightly

different versions for each type of study, but both cover the size and representativeness of the sample as well as the quality of outcome measures. A version is also available for mirror-image or before-and-after studies without a comparison group. The Joanna Briggs Institute also provides checklists for the appraisal of a broad range of study designs, as does the National Institute of Health (see Table 1).

In addition to assessing the methodological quality of individual studies, it is also possible to assess the quality of the overall evidence using Grades of Recommendation, Assessment, Development and Evaluation. This covers directness of evidence, heterogeneity, precision of effect estimates, and risk of publication bias for each outcome (see the following section) as well as the risk of bias in individual studies.

Quality is graded into four levels, the highest score being for evidence from RCTs. Observational studies without special strengths provide low-quality evidence. However, within this group, rigorous observational studies provide stronger evidence than uncontrolled case series. In addition, grades can fall or rise based on factors such as the use of controls, presence of blinding, or levels of attrition.

Publication Bias

Publication bias occurs because large studies with statistically significant results are more likely to be published and cited, and these are often preferentially published in English. Large nonsignificant studies, or small ones with positive findings, are the next most likely to be published. Small nonsignificant studies are least likely. Availability of studies may also vary from being actively disseminated (e.g., pharmaceutical company-sponsored trials), easily available (e.g., open-access electronic journals), available in principle (e.g., limited-circulation print journals), or unavailable (e.g., unpublished data). These biases can be assessed with the fail-safe N or funnel plots. The fail-safe N statistic is the number of nonsignificant studies necessary to reduce the OR or affect size to a negligible value. It can be calculated using WINPEPI. Funnel plots can be obtained using RevMan, with asymmetry suggesting publication bias. Large studies are clustered at the top of the graph, whereas smaller ones are dispersed at the bottom of the graph, as there is more random variation in small studies. At least 10 studies are generally required for accurately estimating publication bias.

In the absence of publication bias, the resulting plot resembles a triangle or funnel. However, if there is bias, the bottom of the plot is asymmetrical with more studies on the right than on the left, where small nonsignificant studies should appear. Programs such as WINPEPI

can also compute the following significance tests for a skewed funnel plot where low p values suggest publication bias: the regression asymmetry test or the adjusted rank correlation test. It is possible to adjust for publication bias through techniques such as Sue Duval and Richard Tweedie's trim and fill method. These techniques impute missing studies and then recalculate the effect size.

Exploration of Effect Modifiers and/or Confounders in Meta-analyses

It is possible to address the effect of moderator variables such as age, sex, type of intervention by including data by subgroup (e.g., male *versus* female) in software packages such as RevMan. Meta-regression is a more sophisticated approach to examine the impact of moderator variables on study effect size. This uses regression-based techniques to adjust for the effect of multiple variables in the one analysis—it is unavailable in RevMan but included in other freeware, commercial software and plug-ins for statistical packages (see Table 1).

Advanced Techniques

Many of the techniques discussed previously in this entry apply to the pairwise analysis of data from RCTs in which randomization has minimized bias from known and unknown confounders. These are less applicable to other study designs and/or to comparisons of multiple interventions.

Direct Entry of Estimates and Their Standard Errors

The analyses described previously rely on the presence of raw dichotomous or continuous outcomes for the pairwise comparisons of two groups (e.g., intervention or cases *versus* controls). However, observational studies commonly report outcomes as effect sizes, which have been adjusted for confounders. This is less of an issue in RCTs, given that known or unknown confounders should be equally distributed between the study arms, but important for observational studies where the use of raw data would be inappropriate when adjusted effect sizes are available.

In this situation, several software packages allow the direct input of effect sizes, such as the generic inverse variance option in RevMan. It is even possible to combine different types of effect size as there a number of online calculators (see Table 1) for the computation and conversion of different effect sizes such as the

correlation r value, F value from analyses of variance, Cohen's d , Hedges' g , and standardized β coefficients. Online calculators also allow the derivation of effect sizes from the results of t tests or *chi-square* tests.

Before-and-After Studies Without Controls

Before-and-after studies without controls offer other challenges. The application of meta-analyses to these data has been criticized because it is impossible to exclude regression to the mean and the possibility that any change is due to natural recovery or other processes. Another drawback is that pretest outcomes are not independent of posttest measures. This means that any analysis must adjust for the correlation between the two scores. Unfortunately, this information is rarely provided in individual studies, meaning that reviewers must estimate a value. One approach is to use collected reports of correlations that have been previously published. However, this is based on an average and may be of limited applicability to any given study, especially as there may be wide variations in effect size depending on the r value. If a meta-analysis of such data is attempted, there should be a sensitivity analysis of the effect of using a range of values for r .

Network Meta-Analyses (NMAs)

NMAs extend pairwise analyses to more than two interventions. These allow comparisons with both a control group and other active interventions. For instance, NMAs can compare the effectiveness of multiple drugs such as antidepressants. These result in network plots that include both direct pairwise analyses and indirect comparisons, where the effects of two interventions are compared to a common third group. Interventions can also be ranked in order of effect often through the use of a cumulative ranking curve. It is also important to assess the consistency of direct and indirect effects. One statistical method is the weighted average of H , which is an adaptation of the *chi-square* statistic (Q) that incorporates indirect comparisons.

“META-ANALYSIS OF PSYCHOTHERAPY OUTCOME STUDIES”

The article “Meta-Analysis of Psychotherapy Outcome Studies,” written by Mary Lee Smith and Gene Glass and published in *American Psychologist* in 1977, initiated the use of meta-analysis as a statistical tool capable of summarizing the results of numerous studies addressing a single topic. In meta-analysis, individual research studies are identified according to established

criteria and treated as a population, with results from each study subjected to coding and entered into a database, where they are statistically analyzed. Smith and Glass pioneered the application of meta-analysis in research related to psychological treatment and education. Their work is considered a major contribution to the scientific literature on psychotherapy and has spurred hundreds of other meta-analytic studies since its publication.

Historical Context

Smith and Glass conducted their research both in response to the lingering criticisms of psychotherapy lodged by Hans Eysenck beginning in 1952 and in an effort to integrate the increasing volume of studies addressing the efficacy of psychological treatment. In a scathing review of psychotherapy, Eysenck had asserted that any benefits derived from treatment could be attributed to the spontaneous remission of psychological symptoms rather than to the therapy applied. His charge prompted numerous studies on the efficacy of treatment, often resulting in variable and conflicting findings.

Prior to the Smith and Glass article, behavioral researchers were forced to rely on a narrative synthesis of results or on an imprecise tallying method to compare outcome studies. Researchers from various theoretical perspectives highlighted studies that supported their work and dismissed or disregarded findings that countered their position. With the addition of meta-analysis to the repertoire of evaluation tools, however, researchers were able to objectively evaluate and refine their understanding of the effects of psychotherapy and other behavioral interventions. Smith and Glass determined that, on average, an individual who had participated in psychotherapy was better off than 75% of those who were not treated. Reanalyses of the Smith and Glass data, as well as more recent meta-analytic studies, have yielded similar results.

Effect Size

Reviewing 375 studies on the efficacy of psychotherapy, Smith and Glass calculated an index of effect size to determine the impact of treatment on patients who received psychotherapy versus those assigned to a control group. The effect size was equal to the difference between the means of the experimental and control groups divided by the standard deviation of the control group. A positive effect size communicated the efficacy of a psychological treatment in standard deviation units. Smith and Glass found an effect size of .68, indicating that after psychological treatment, individuals

who had completed therapy were superior to controls by .68 standard deviations, an effect size that is generally classified as moderately large.

Other Findings

While best known for its contribution to research on the general efficacy of psychotherapy, the Smith and Glass study also examined relative efficacy of specific approaches to therapy by classifying studies into 10 theoretical types and calculating an effect size for each. Results indicated that approximately 10% of the variance in the effects of treatment could be attributed to the type of therapy employed, although the results were confounded by differences in the individual studies, including the number of variables, the duration of treatment, the severity of the presenting problem, and the means by which progress was evaluated. The authors attempted to address these problems by collapsing the 10 types of therapies into four classes: ego therapies, dynamic therapies, behavioral therapies, and humanistic therapies, and then further collapsing the types of therapy into two superclasses labeled *behavioral* and *nonbehavioral* therapies. They concluded that differences among the various types of therapy were negligible. They also asserted that therapists' degrees and credentials were unrelated to the efficacy of treatment, as was the length of therapy.

Criticisms

Publication of the Smith and Glass article prompted a flurry of responses from critics, including Eysenck, who argued that the studies included in the meta-analysis were too heterogeneous to be compared and that many were poorly designed. Some critics pointed out that an unspecified proportion of studies included in the analysis did not feature an untreated control group. Further, some studies did not have a placebo control group to rule out the effects of attention or expectation among patients. A later reanalysis of the data by Janet Landman and Robyn Dawes published in 1982 used more stringent criteria and featured separate analyses that used only studies that included placebo controls. Their analyses reached conclusions that paralleled those of Smith and Glass.

Influence

The Smith and Glass study not only altered the landscape of the psychotherapeutic efficacy battle; it also laid the groundwork for meta-analytic studies investigating a variety of psychological and educational interventions. Their work provided an objective means of

determining the outcome of a given intervention, summarizing the results of large numbers of studies, and indicating not only whether a treatment makes a difference, but how much of a difference.

At the time of the Smith and Glass publication, the statistical theory of meta-analysis was not yet fully articulated. More recent studies using meta-analysis have addressed the technical problems found in earlier work. As a result, meta-analysis has become an increasingly influential technique in measuring treatment efficacy.

METHOD VARIANCE

Method is what is used in the process of measuring something, and it is a property of the measuring instrument. The term *method effects* refers to the systematic biases caused by the measuring instrument. *Method variance* refers to the amount of variance attributable to the methods that are used. In psychological measures, method variance is often defined in relationship to trait variance. *Trait variance* is the variability in responses due to the underlying attribute that one is measuring. In contrast, method variance is defined as the variability in responses due to

characteristics of the measuring instrument. After sketching a short history of method variance, this entry discusses features of measures and method variance analyses and describes approaches for reducing method effects.

A Short History

No measuring instrument is free from error. This is particularly germane in social science research, which relies heavily on self-report instruments. Donald Thomas Campbell was the first to mention the problem of method variance. In 1959, Campbell and Donald W. Fiske described the fallibility inherent in all measures and recommended the use of multiple methods to reduce error. Because no single method can be the gold standard for measurement, they proposed that multiple methods be used to triangulate on the underlying “true” value. The concept was later extended to unobtrusive measures.

Method variance has not been well defined in the literature. The assumption has been that the reader knows what is meant by *method variance*. It is often described in a roundabout way, in relationship to trait variance. Campbell and Fiske pointed out that there is no fixed demarcation between trait and method. Depending on the goals of a particular research project, a characteristic may be considered either a method or a trait. Researchers have reported the methods that they use as different tests, questionnaires with different types of answers, self-report and peer ratings, clinician reports, or institutional records, to name a few.

In 1950 Campbell differentiated between structured and nonstructured measures, along with those whose intent was disguised, versus measures that were obvious to the test taker. Later Campbell and others described the characteristics associated with unobtrusive methods, such as physical traces and archival records. More recently, Lee Sechrest and colleagues extended this characterization to observable methods.

Others have approached the problem of method from an “itemetric” level, in paper-and-pencil questionnaires. A. Angleitner, O. P. John, and F. Löhr proposed a series of item-level characteristics, including overt reactions, covert reactions, bodily symptoms, wishes and interests, attributes of traits, attitudes and beliefs, biographical facts, others’ reactions, and bizarre items.

Obvious Methods

There appear to be obvious, or manifest, features of measurement, and these include stimulus formats,

response formats, response categories, raters, direct rating versus summative scale, whether the stimulus or response is rated, and finally, opaque versus transparent measures. These method characteristics are usually mentioned in articles to describe the methods used. For example, an abstract may describe a measure as “a 30-item true–false test with three subscales,” “a structured interview used to collect school characteristics,” or “patient functioning assessed by clinicians using a 5-point scale.”

Stimulus and Response Formats

The stimulus format is the ways the measure is presented to the participant, such as written or oral stimulus. The response format refers to the methods used to collect the participant’s response and includes written, oral, and graphical approaches. The vast majority of stimulus and response formats used in social science research are written paper-and-pencil tests.

Response Categories

The response categories include the ways an item may be answered. Examples of response categories include multiple-choice items, matching, Likert-type scales, true–false answers, responses to open-ended questions, and visual analogue scales. Close-ended questions are used most frequently, probably because of their ease of administration and scoring. Open-ended questions are used less frequently in social science research. Often the responses to these questions are very short, or the question is left blank. Open-ended questions require extra effort to code. Graphical responses such as visual analogue scales are infrequently used.

Raters

Raters are a salient method characteristic. Self-report instruments comprise the majority of measures. In addition to the self as rater, other raters include, for example, teachers, parents, and peers. Other raters may be used in settings with easy access to them. For example, studies conducted in schools often include teacher ratings and may collect peer and parent ratings. Investigations in medical settings may include ratings by clinicians and nurses.

The observability of the trait in question probably determines the accuracy of the ratings by others. An easily observable trait such as extroversion will probably generate valid ratings. However, characteristics that cannot be seen, particularly those that the respondent chooses to hide, will be harder to rate. Racism is

a good example of a characteristic that may not be amenable to ratings.

Direct Versus Summative Scale

This method characteristic refers to the number of items used to measure a characteristic. The respondent may be asked directly about his or her standing on a trait; for example, How extroverted are you? In other instances, multiple-item scales are employed. The items are then summed to estimate the respondent's standing on the trait. Direct, single items may be sufficient if a trait is obvious and/or the respondent does not care about the results.

Rating the Stimulus Versus Rating the Response

Rating the prestige of colleges or occupations is an example of rating the stimulus; self-report questionnaires for extroversion or conscientiousness are examples of rating the response. The choice depends on the goals of the study.

Opaque Versus Transparent Measures

This method characteristic refers to whether the purpose of a test is easily discerned by the respondent. The Stanford-Binet is obviously a test of intelligence, and the Myers-Briggs Type Indicator inventory measures extroversion. These are transparent tests. If the respondent cannot easily guess the purpose of a test, it is opaque.

Types of Analyses Used for Method Variance

If a single method is used, it is not possible to estimate method effects. Multiple methods are required in an investigation in order to study method effects. When multiple methods are collected, they must be combined in some way to estimate the underlying trait. Composite scores or latent factor models are used to estimate the trait. If the measures in a study have used different sources of error, the resulting trait estimate will contain less method bias.

Estimating the effect of methods is more complicated. Neal Schmitt and Daniel Stutts have provided an excellent summary of the types of analyses that may be used to study method variance. Currently, the most popular method of analysis for multitrait-multimethod matrices is *confirmatory factor analysis*. However, there are a variety of problems inherent in this method,

and *generalizability theory analysis* shows promise for multitrait-multimethod data.

Does Method Variance Pose a Real Problem?

The extent of variance attributable to methods has not been well studied, although several interesting articles have focused on it. Joseph A. Cote and M. Ronald Buckley examined 70 published studies and reported that trait accounted for more than 40% of the variance and method accounted for approximately 25%. D. Harold Doty and William H. Glick obtained similar results.

Reducing Effects of Methods

A variety of approaches can be used to lessen the effects of methods in research studies. Awareness of the problem is an important first step. The second is to avoid measurement techniques laden with method variance. Third, incorporate multiple measures that use maximally different methods, with different sources of error variance. Finally, the multiple measures can be combined into a trait estimate during analysis. Each course of action reduces the effects of methods in research studies.

METHODS SECTION

The purpose of a methods section of a research paper is to provide the information by which a study's validity is judged. It must contain enough information so that (a) the study could be repeated by others to evaluate whether the results are reproducible, and (b) others can judge whether the results and conclusions are valid. Therefore, the methods section should provide a clear and precise description of how a study was done and the rationale for the specific procedures chosen.

Historically, the methods section was referred to as the “materials and methods section” to emphasize the two areas that must be addressed. “Materials” referred to what was studied (e.g., humans, animals, tissue cultures), treatments applied, and instruments used. “Methods” referred to the selection of study subjects, data collection, and data analysis. In some fields of study, because “materials” does not apply, alternative headings such as “subjects and methods,” “patients and methods,” or simply “methods” have been used or recommended.

Below are the items that should be included in a methods section.

Subjects or Participants

If human or animal subjects were used in the study, who the subjects were and how they were relevant to the research question should be described. Any details that are relevant to the study should be included. For humans, these details include gender, age, ethnicity, socioeconomic status, and so forth, when appropriate. For animals, these details include gender, age, strain, weight, and so forth. The researcher should also describe how many subjects and how they were selected. The selection criteria and rationale for enrolling subjects into the study must be stated explicitly. For example, the researcher should define study and comparison subjects and the inclusion and exclusion criteria of subjects. If the subjects were human, the type of reward or motivation used to encourage them to

participate should be stated. When working with human or animal subjects, there must be a declaration that an ethics or institutional review board has determined that the study protocol adheres to ethical principles. In studies involving animals, the preparations made prior to the beginning of the study must be specified (e.g., use of sedation and anesthesia).

Study Design

The design specifies the sequence of manipulations and measurement procedures that make up the study. Some common designs are experiments (e.g., randomized trials, quasi-experiments), observational studies (e.g., prospective or retrospective cohort, case–control, cross-sectional), qualitative methods (e.g., ethnography, focus groups) and others (e.g., secondary data analysis, literature review, meta-analysis, mathematical derivations, and opinion–editorial pieces). Here is a brief description of the designs. Randomized trials involve the random allocation by the investigator of subjects to different interventions (treatments or conditions). Quasi-experiments involve nonrandom allocation. Both cohort (groups based on exposures) and case–control (groups based on outcomes) studies are longitudinal studies in which exposures and outcomes are measured at different times. Cross-sectional studies measure exposures and outcomes at a single time. Ethnography uses fieldwork to provide a descriptive study of human societies. A focus group is a form of qualitative research in which people assembled in a group are asked about their attitude toward a product or concept. An example of secondary data is the abstraction of data from existing administrative databases. A meta-analysis combines the results of several studies that address a set of related research hypotheses.

Data Collection

The next step in the methods section is a description of the variables that were measured and how these measurements were made. In laboratory and experimental studies, the description of measurement instruments and reagents should include the manufacturer and model, calibration process, and how measurements were made. In epidemiologic and social studies, the development and pretest of questionnaires, training of interviewers, data extraction from databases, and conduct of focus groups should be described where appropriate. In some cases, the survey instrument (questionnaire) may be included as an appendix to the research paper.

Data Analysis

The last step in the methods section is to describe the way in which the data will be presented in the results section. For quantitative data, this step should specify whether and which statistical tests will be used for making the inference. If statistical tests are used, this part of the methods section must specify the significance level and whether one- or two-sided or the type of confidence intervals. For qualitative data a common analysis is observer impression. That is, expert or lay observers examine the data, form an impression, and report their impression in a structured, quantitative form.

The following are some tips for writing the methods section: (a) The writing should be direct and precise. Complex sentence structures and unimportant details should be avoided. (b) The rationale or assumptions on which the methods are based may not always be obvious to the audience and so should be explained clearly. This is particularly true when one is writing for a general audience, as opposed to a subspecialty group. The writer must always keep in mind who the audience is. (c) The methods section should be written in the past tense. (d) Subheadings, such as participants, design, and so forth, may help readers navigate the paper. (e) If the study design is complex, it may be helpful to include a diagram, table, or flowchart to explain the methods used. (f) Results should not be placed in the methods section. However, the researchers may include preliminary results from a pilot test they used to design the main study they are reporting.

The methods section is important because it provides the information the reader needs to judge the study's validity. It should provide a clear and precise description of how a study was conducted and the rationale for specific study methods and procedures.

MISSING DATA, IMPUTATION OF

Imputation involves replacing missing values, or *missings*, with an estimated value. In a sense, imputation is a prediction solution. It is one of three options for handling missing data—besides ignoring them when possible. The general principle is to delete when the data are expendable, impute when the data are precious, and segment on missing *versus* nonmissing when this is informative. When measured against deletion, imputation often affords more accurate results. This entry discusses the differences between imputing and deleting, the types of missings, the criteria for preferring imputation, and various imputation techniques. It closes with application suggestions.

Impute or Delete

The trade-off is between convenience and bias. There are two choices for deletion (casewise or pairwise) and several approaches to imputation. *Casewise deletion* omits the entire observation (or case), for all of the variables when it is missing for any variable. This sacrifices partial information, contained in the other variables, either for convenience or to accommodate certain statistical techniques. Techniques such as structural equation modeling may require complete data for all the variables, so only casewise deletion is possible for them. *Pairwise deletion* omits observations on a variable-by-variable basis. For techniques like calculating correlation coefficients, pairwise deletion will leverage the partial information of the observations, which can be advantageous for small sample sizes and when missings are not at random.

Imputation is usually the more advantageous technique when (a) the missings are not random, (b) the missings represent a large proportion of the data set, or (c) the data set is small or otherwise precious. If the missings do not occur at random, which is the most common situation, then deleting can create significant bias. For some situations, it is possible to repair the bias through weighting—as in poststratification for surveys. If the data set is small or otherwise precious, then deleting can severely reduce the statistical power or value of the data analysis.

Imputation can repair the missing data by creating one or more versions of how the data set should appear. By leveraging external knowledge, and/or good technique, it is possible to reduce the bias due to missing values. Some techniques offer a quick improvement over deletion. Software is making these techniques faster and sharper. However, improved software is facilitating more low-quality data analysis by enabling

those without appropriate training and sufficient governance. Even with software, training, and experience, imputation may require as much effort as building the model that uses the imputed values.

Categorizing Missingness

Missingness can be categorized in two ways: the physical structure of the missings and the underlying nature of the missingness. First, the structure of the missings can be due to item or unit missingness; a merge of structurally different data sets or limitations attributable to the data collection tools. Item missingness refers to the situation in which a single value is missing for a particular observation, and unit missingness refers to the situation in which all the values for an observation are missing.

Second, missings can be categorized by the underlying nature of the missingness. The three categories are (1) missing completely at random (MCAR), (2) missing at random (MAR), and (3) missing not at random (MNAR), summarized in Table 1 and discussed below.

Categorizing missings into one of these three groups supports better judgment as to the most appropriate imputation technique and the ramifications of employing that technique. MCAR is the least common, yet the easiest to address. Deletion and multiple imputation should provide unbiased results. MAR is better thought of as missing partially at random; the point is that there is some pattern that can be leveraged. There are many imputation techniques geared toward MAR. For MAR, ignoring the missings leads to biased results and imputation does not. There are statistical tests for inferring MCAR and MAR. The potential of these techniques depends on the degree to which other variables are

related to the missings. MNAR is also known and better described as informative missing, nonignorable missingness. It is the most difficult to address. The most promising approach is to use external data to identify and repair this problem.

Statistical and Contextual Diagnosis

Analyzing the missings and understanding their context can help researchers infer whether they are MCAR, MAR, or MNAR. This section discusses five considerations: (1) relationships between the missings and other variables, (2) concurring missing patterns, (3) relationships between variables and external information, (4) context of the analysis, and (5) software.

Relationships Between the Missings and Other Variables

Exploratory data analysis will reveal relationships that can indicate MAR and lead to an appropriate imputation technique. There are statistical tests for comparing the means and distributions of covariates for missings *versus* nonmissings. Statistically significant results infer MAR and therefore discount MCAR. Several techniques are available to help provide insight, including logistic regression, regression trees, and cluster analysis. The insight from this data analysis should be juxtaposed with the context of the application and the source of the data.

Concurring Missing Patterns

Concurring missings suggest a shared event. Placed within context, these can indicate that the missings

Table 1 Underlying Nature of Missingness

Type	Definitions and Examples	Most Likely Approach
Missing completely at random	Missing values occur completely at random with no relationship to themselves or the values of any other variables. For example, suppose researchers can only afford to measure temperature for a randomly selected subsample. The remaining observations will be missing, completely at random.	Delete
Missing at random or missing partially at random	Missing values occur partially at random, occurring relative to observable variables and otherwise randomly. That is, after controlling for all other observable variables, the missing values are random.	Impute
Missing not at random; informative missing	Missing values occur relative to the variable itself and are not random after controlling for all other variables. For example, as temperatures become colder, the thermometer is increasingly likely to fail and other variables cannot fully explain the pattern in these failures.	Impute

were *manufactured* by the data collection tool or the data pipeline or that they convey information about the phenomenon being studied. These clues can infer MCAR, MAR, or MNAR.

Relationships Between Variables and External Information

Comparing the distribution of variables with missing values to external data can reveal that the data are MNAR rather than MCAR. For example, the mean (or distribution) of the nonmissings should be compared to external estimates of the overall mean (or distribution).

Context of the Analysis

It is necessary to study the context of the analysis, including the statistical aspects of the problem and the consequences of various imputation techniques. For example, missings belonging to controlled variables in an experiment have different implications from those of observed variables.

Missing values do not always represent a failure to measure. Sometimes, these are accurate measurements. For example, if amount of loan loss is missing, it could be because the loss amount was not entered into the computer or because the loan never defaulted. In the latter case, the value can be thought of as either zero or as *does not apply*, whichever is more appropriate for the analysis. It is common for collection tools to record a missing value when a zero is more appropriate.

Software

Software has developed beyond that of a simple tool. Researcher's choices are often limited to those techniques supported by available software.

Imputation Techniques

Imputation techniques are optimal when missing values are not all *uncreated* equal, as in MAR. All of the techniques have statistical objectives. Criteria for choosing a technique include the underlying nature of the missings (MCAR, MAR, or MNAR), speed, implications regarding bias and variance estimation, and considerations related to preserving the natural distribution and correlation structure. A final consideration is to avoid extrapolating outside the range space of the data. Some missing values have logical bounds. This section discusses five types of techniques: (1) substitution, (2) regression (least squares), (3) Bayesian methods, (4) maximum likelihood estimation (MLE)/expectation

maximization (EM) algorithm, and (5) multiple imputation.

Substitution Techniques

One quick solution is to substitute, for example, the mean, median, series mean, or a linear interpolation for the missings. One drawback for using the global mean or median is that values are repeated. This can create an awkward spike in the distribution. One way to avoid this is to substitute local means or medians when available. These quick substitutions tend to underestimate the variance and can inflate or deflate correlations.

For categorical variables with missings, characteristic analysis calculates the means of some variables corresponding to each category and means corresponding to the missings. The missings are assigned to the category with the closest means.

Hot deck and *cold deck* are techniques for imputing real data into the missings, with or without replacement. For hot deck, the donor data are from the same data set, and for cold deck, the donor data are from another data set. Hot deck avoids extrapolating outside of the range space of the data set, and it will better preserve the natural distribution than does the imputation of a mean. Both tend to be better for MAR.

Regression (Least Squares)

Regression-based imputation predicts the missings on the basis of ordinary-least-squares or weighted-least-squares modeling of the nonmissing data. This approach assumes that relationships among the nonmissing data will extrapolate to the missing-value space. This technique assumes that the data are MAR and not MCAR. It creates bias depending on the degree to which the model is overfit. As always, validation techniques such as *bootstrapping* or *data splitting* will curb the amount of overfitting.

Regression-based imputation leads to underestimating the variance. Statisticians have studied the addition of random errors to the imputed values as a technique to correct this underestimation. The random errors can come from a designated distribution or from the observed data.

Regression-based imputation does not preserve the natural distribution or respect the associations between variables. Also, it repeats imputed values when the independent variables are identical.

Bayesian Methods

The approximate Bayesian bootstrap uses logistic regression to predict missing and nonmissing values for

the dependent variable y , based on the observed x values. The observations are then grouped on the basis of the probability of the value missing. Candidate imputation values are randomly selected, with replacement, from the same group.

MLE-EM Algorithm

The EM algorithm is an iterative, two-step approach for finding an MLE for imputation. The initial step consists of deriving an expectation based on latent variables. This is followed by a maximization step, computing the MLE. The technique assumes an underlying distribution, such as the normal, mixed normal, or Student's t .

The MLE method assumes that missing values are MAR (as opposed to MCAR) and shares with regression the problem of overfitting. MLE is considered to be stronger than regression while making fewer assumptions.

Multiple Imputation

Multiple imputation leverages other imputation techniques to impute multiple times, creating multiple versions of the data set. Each data set is analyzed and then the results are combined—usually by averaging. The advantages are that this process is easier than MLE, is robust to departures from underlying assumptions, and provides better estimates of variance than regression.

Suggestions for Applications

A project's final results should include reasons for deleting or imputing. It should justify any selected imputation technique and enumerate the corresponding potential biases. As a check, it is advisable to compare the results obtained with and without imputing. This comparison will reveal the effect due to imputation. Finally, there is an opportunity to clarify whether the missings provide an additional hurdle or valuable information.

MIXED- AND RANDOM-EFFECTS MODELS

Data that are collected or generated in the context of any practical problem always exhibit variability. This variability calls for the use of appropriate statistical methodology for the data analysis. Data that are obtained from designed experiments are typically analyzed using a model that takes into consideration the various sources or *factors* that could account for the variability in the data. Here the term *experiment* denotes the process by which data are generated based on the basis of planned changes in one or more input variables that are expected to influence the response. The plan or layout used to carry out the experiment is referred to as an *experimental design* or *design of the experiment*. The analysis of the data is based on an appropriate statistical model that accommodates the various factors that explain the variability in the data. If all the factors are fixed, that is, nonrandom, the model is referred to as a *fixed-effects model*. If all the factors are random, the model is referred to as a *random-effects model*. On the other hand, if the experiment involves fixed as well as random factors, the model is referred to as a *mixed-effects model*. In this entry, mixed- as well as random-effects models are introduced through some simple research design examples. Data analysis based on such models is briefly commented on.

A Simple Random-Effects Model

Here is a simple example, taken from Douglas C. Montgomery's book on experimental designs. A manufacturer wishes to investigate the research question of whether batches of raw materials furnished by a supplier differ significantly in their calcium content. Suppose data on the calcium content will be obtained on five batches that were received in 1 day. Furthermore, suppose six determinations of the calcium content will be made on each batch. Here *batch* is an input variable, and the response is the calcium content. The input variable is also called a *factor*. This is an example of a single-factor experiment, the factor being *batch*. The different possible categories of the factor are referred to as *levels* of the factor. Thus the factor *batch* has five

levels. Note that on each level of the factor (i.e., on each batch), we obtain the same number of observations, namely six. In such a case, the data are called *balanced*. In some applications, it can happen that the numbers of observations obtained on each level of the factor are not the same; that is, we have unbalanced data.

In the above example, suppose the purpose of the data analysis is to test whether there is any difference in the calcium content among five given batches of raw materials obtained in one day. In experimental design terminology, we want to test whether the five batches have the same *effects*. This example, as stated, involves a factor (namely batch) having *fixed effects*. The reason is that there is nothing random about the batches themselves; the manufacturer has five batches given to him on a single day, and he wishes to make a comparison of the calcium content among the five given batches. However, there are many practical problems in which the factor could have random effects. In the context of the same example, suppose a large number of batches of raw materials are available in the warehouse, and the manufacturer does not have the resources to obtain data on all the batches regarding their calcium content. A natural option in this case is to collect data on a sample of batches, randomly selected from the population of available batches. Random selection is done to ensure that we have a representative sample of batches. Note that if another random selection is made, a different set of five batches could have been selected. If five batches are selected randomly, we then have a factor having *random effects*. Note that the purpose of our data analysis is not to draw conclusions regarding the calcium content of the five batches randomly selected; rather, we would like to use the random sample of five batches to draw conclusions regarding the population of all batches. The difference between fixed effects and random effects should now be clear. In the fixed-effects case, we have a given number of levels of a factor, and the purpose of the data analysis is to make comparisons among these given levels only, based on the responses that have been obtained. In the random-effects case, we make a random selection of a few levels of the factor (from a population of levels), and the responses are obtained on the randomly selected levels only. However, the purpose of the analysis is to make inferences concerning the population of all levels.

In order to make the concepts more concrete, let y_{ij} denote the j th response obtained on the i th level of the factor, where $j = 1, 2, \dots, n$, and $i = 1, 2, \dots, a$. Here a denotes the number of levels of the factor, and n denotes the number of responses obtained on each level. For our example, $a=5$, $n=6$, and y_{ij} is the j th determination of the calcium content from the i th batch of

raw material. The data analysis can be done assuming the following structure for the y_{ij} s, referred to as a model:

$$y_{ij} = \mu + \tau_i + e_{ij}, \quad (1)$$

where μ is a common mean, the quantity τ_i represents the effect due to the i th level of the factor (effect due to the i th batch), and e_{ij} represents experimental error. The e_{ij} s are assumed to be random, following a normal distribution with mean zero and variance σ^2 . In the fixed-effects case, the τ_i s are fixed unknown parameters, and the problem of interest is to test whether the τ_i s are equal. The model for the y_{ij} is now referred to as a *fixed-effects model*. In this case, the restriction $\sum_{i=1}^a \tau_i = 0$ can be assumed, without loss of generality. In the random-effects case, the τ_i s are assumed to be random variables following a normal distribution with mean zero and variance σ_τ^2 . The model for the y_{ij} is now referred to as a *random-effects model*. Note that σ_τ^2 is a population variance; that is, it represents the variability among the population of levels of the factor. Now the problem of interest is to test the hypothesis that σ_τ^2 is zero. If this hypothesis is accepted, then the conclusion is that the different levels of the factor do not exhibit significant variability among them. In the context of the example, if the batches are randomly selected, and if the hypothesis $\sigma_\tau^2=0$ is not rejected, then the data support the conclusion that there is no significant variability among the different batches in the population.

Mixed- and Random-Effects Models for Multifactor Experiments

In the context of the same example, suppose the six calcium content measurements on each batch are made by six different operators. While carrying out the measuring process, there could be differences among the operators. In other words, in addition to the effect due to the batches, there exist effects due to the operators as well, accounting for the differences among them. A possible model that could capture both the batch effects and the operator effects is

$$y_{ij} = \mu + \tau_i + \beta_j + e_{ij}, \quad (2)$$

$i=1, 2, \dots, a$, $j=1, 2, \dots, b$, where y_{ij} is the calcium content measurement obtained from the i th batch by the j th operator; β_j is the effect due to the j th operator; and μ , the τ_i s, and the e_{ij} s are as defined before. In the context of the example, $a=5$ and $b=6$. Now there are two input variables, that is, batches and operators, that are expected to influence the response (i.e., the calcium content measurement). This is an example of a two-factor experiment. Note that if the batches as well as

the operators are randomly selected, then the τ_i s, as well as the β_j s, become random variables; the above model is then called a random-effects model. However, if only the batches are randomly selected (so that the τ_i s are random), but the measurements are taken by a given group of operators (so that the β_j s are fixed unknown parameters), then we have a mixed-effects model. That is, the model involves fixed effects corresponding to the given levels of one factor and random-effects corresponding to a second factor, whose levels are randomly selected. When the β_j s are fixed, the restriction $\sum_{j=1}^b \beta_j = 0$ may be assumed. For a random-effects model, independent normal distributions are typically assumed for the τ_i s, for the β_j s, and the e_{ijk} s, similar to that for Model 1. When the effects due to a factor are random, the hypothesis of interest is whether the corresponding variance is zero. In the fixed-effects case, we test whether the effects are the same for the different levels of the factor.

Note that Model 2 makes a rather strong assumption, namely, that the combined effect due to the two factors, batch and operator, can be written as the sum of an effect due to the batch and an effect due to the operator. In other words, there is *no interaction* between the two factors. In practice, such an assumption may not always hold when responses are obtained based on the combined effects of two or more factors. If interaction is present, the model should include the combined effect due to the two factors. However, now multiple measurements are necessary to carry out the data analysis. Thus, suppose each operator makes three determinations of the calcium content on each batch. Denote by y_{ijk} the k th calcium content measurement on the i th batch by the j th operator. When there is interaction, the assumed model is

$$y_{ijk} = \mu + \tau_i + \beta_j + \gamma_{ij} + e_{ijk}, \quad (3)$$

where $i=1, 2, \dots, a$; $j=1, 2, \dots, b$; and $k=1, 2, \dots, n$ (say). Now τ_i represents an average effect due to the i th batch. In other words, consider the combined effect due to the i th batch and the j th operator, and average it over $j = 1, 2, \dots, b$. We refer to τ_i as the *main effect* due to the i th batch. Similarly, β_j is the main effect due to the j th operator. The quantity γ_{ij} is the interaction between the i th batch and the j th operator. If a set of given batches and operators is available for the experiment (i.e., there is no random selection), then the τ_i s, β_j s, and γ_{ij} s are all fixed, and Equation 3 is then a fixed-effects model. On the other hand, if the batches are randomly selected, whereas the operators are given, then the τ_i s and γ_{ij} s are random, but the β_j s are fixed. Thus Model 3 now becomes a mixed-effects model. However, if the batches and operators are both

randomly selected, then all the effects in Equation 3 are random, resulting in a random-effects model. Equation 3 is referred to as a *two-way classification model with interaction*. If the batches are randomly selected, whereas the operators are given, then a formal derivation of Model 3 will result in the conditions $\sum_{j=1}^b \beta_j = 0$ and $\sum_{j=1}^b \gamma_{ij} = 0$ for every i . That is, the random variables γ_{ij} s satisfy a restriction. In view of this, the γ_{ij} s corresponding to a fixed i will not be independent among themselves. The normality assumptions are typically made on all the random quantities.

In the context of Model 1, note that two observations from the same batch are correlated. In fact σ_τ^2 is also the covariance between two observations from the same batch. Other examples of correlated data where mixed- and random-effects models are appropriate include longitudinal data, clustered data, and repeated measures data. By including random-effects in the model, it is possible for researchers to account for multiple sources of variation. This is indeed the purpose of using mixed- and random-effects models for analyzing data in the physical and engineering sciences, medical and biological sciences, social sciences, and so forth.

Data Analysis Based on Mixed- and Random-Effects Models

When the same number of observations is obtained on the various level combinations of the factors, the data are said to be balanced. For Model 3, balanced data correspond to the situation in which exactly n calcium content measurements (say, $n=6$) are obtained by each operator from each batch. Thus the observations are y_{ijk} ; $k=1, 2, \dots, n$; $j=1, 2, \dots, b$; and $i=1, 2, \dots, a$. On the other hand, unbalanced data correspond to the situation in which the number of calcium content determinations obtained by the different operators are not all the same for all the batches. For example, suppose there are five operators, and the first four make six measurements each on the calcium content from each batch, whereas the fifth operator could make only three observations from each batch because of time constraints; we then have unbalanced data. It could also be the case that an operator, say the first operator, makes six calcium content determinations from the first batch but only five each from the remaining batches. For unbalanced data, if n_{ij} denotes the number of calcium content determinations made by the j th operator on the i th batch, the observations are y_{ijk} ; $k=1, 2, \dots, n_{ij}$; $j=1, 2, \dots, b$; and $i=1, 2, \dots, a$. The analysis of unbalanced data is considerably more complicated under mixed- and random-effects models, even under normality assumptions. The case of balanced data is somewhat simpler.

Analysis of Balanced Data

Consider the simple Model 1 with balanced data, along with the normality assumptions for the distribution of the τ_i s and the e_{ij} s with variances σ_τ^2 and σ_e^2 , respectively. The purpose of the data analysis can be to estimate the variances σ_τ^2 and σ_e^2 , to test the null hypothesis that $\sigma_\tau^2 = 0$, and to compute a confidence interval for σ_τ^2 and sometimes for the ratios $\sigma_\tau^2 / \sigma_e^2$ and $\sigma_\tau^2 / (\sigma_\tau^2 + \sigma_e^2)$. Note that the ratio $\sigma_\tau^2 / \sigma_e^2$ provides information on the relative magnitude of σ_τ^2 compared with that of σ_e^2 . If the variability in the data is mostly due to the variability among the different levels of the factor, σ_τ^2 is expected to be large compared with σ_e^2 , and the hypothesis $\sigma_\tau^2 = 0$ is expected to be rejected. Also note that since the variance of the observations, that is, the variance of the y_{ij} s in Model 1, is simply the sum $\sigma_\tau^2 + \sigma_e^2$, the ratio $\sigma_\tau^2 / (\sigma_\tau^2 + \sigma_e^2)$ is the fraction of the total variance that is due to the variability among the different levels of the factor. Thus the individual variances as well as the above ratios have practical meaning and significance.

Now consider Model 3 with random effects and with the normality assumptions $\tau_i \sim N(0, \sigma_\tau^2)$, $\beta_j \sim N(0, \sigma_\beta^2)$, $\gamma_{ij} \sim N(0, \sigma_\gamma^2)$, and $e_{ijk} \sim N(0, \sigma_e^2)$, where all the random variables are assumed to be independently distributed. Now the problems of interest include the estimation of the different variances and testing the hypothesis that the random-effects variances are zeros. For example, if the hypothesis $\sigma_\gamma^2 = 0$ cannot be rejected, we conclude that there is no significant interaction. If Model 3 is a mixed-effects model, then the normality assumptions are made on the effects that are random. Note, however, that the γ_{ij} s, although random, will no longer be independent in the mixed-effects case, in view of the restriction $\sum_{j=1}^b \gamma_{ij} = 0$ for every i .

The usual analysis of variance (ANOVA) decomposition can be used to arrive at statistical procedures to address all the above problems. To define the various ANOVA sums of squares for Model 3 in the context of our example on calcium content determination from different batches using different operators, let

$$\begin{aligned}\bar{y}_{ij.} &= \frac{1}{n} \sum_{k=1}^n y_{ijk}, \bar{y}_{i..} = \frac{1}{bn} \sum_{j=1}^b \sum_{k=1}^n y_{ijk}, \bar{y}_{.j.} \\ &= \frac{1}{an} \sum_{i=1}^a \sum_{k=1}^n y_{ijk}, \bar{y}_{...} = \frac{1}{abn} \sum_{i=1}^a \sum_{j=1}^b \sum_{k=1}^n y_{ijk}.\end{aligned}$$

If SS_τ , SS_β , SS_γ , and SS_e denote the ANOVA sum of squares due to the batches, operators, interaction, and error, respectively, these are given by

$$\begin{aligned}SS_\tau &= bn \sum_{i=1}^a (\bar{y}_{i..} - \bar{y}_{...})^2, SS_\beta = an \sum_{j=1}^b (\bar{y}_{.j.} - \bar{y}_{...})^2 \\ SS_\gamma &= n \sum_{i=1}^a \sum_{j=1}^b (\bar{y}_{ij.} - \bar{y}_{i..})^2 - SS_\tau - SS_\beta, \\ SS_e &= \sum_{i=1}^a \sum_{j=1}^b \sum_{k=1}^n (y_{ijk} - \bar{y}_{ij.})^2.\end{aligned}$$

The following table shows the ANOVA table and the expected mean squares in the mixed-effects case and in the random-effects case; these are available in a number of books dealing with mixed- and random-effects models, in particular in Montgomery's book on experimental designs. In the mixed-effects case, the β_j s are fixed, but the τ_i s and γ_{ij} s are random. In other words, the batches are randomly selected, but the operators consist of a fixed group. In the random-effects case, the β_j s, the τ_i s, and the γ_{ij} s are all random. In the table, the notations MS_τ and so forth are used to denote mean squares.

Note that the expected values can be quite different depending on whether we are in the mixed-effects setup or the random-effects setup. Also, when an expected value is a linear combination of only the variances, then the sum of squares, divided by the expected value, has a chi-square distribution. For example, in Table 1, in the mixed-effects case, $SS_\tau / (\sigma_e^2 + bn\sigma_\tau^2)$ follows a chi-square distribution with $a - 1$ degrees of freedom. However, if an expected value also involves the fixed-effects parameters, then the chi-square distribution holds under the appropriate hypothesis concerning the fixed effects. Thus, in Table 1, in the mixed-effects case, $SS_\beta / (\sigma_e^2 + n\sigma_\gamma^2)$ follows a chi-square distribution with $b - 1$ degrees of freedom, under the hypothesis $\beta_1 = \beta_2 = \dots = \beta_b = 0$. Furthermore, for testing the various hypotheses, the denominator of the F ratio is not always the mean square due to error. If one compares the expected values in Table 1, one can see that for testing $\sigma_\tau^2 = 0$ in the mixed-effects case, the F ratio is MS_τ / MS_e . However, for testing $\beta_1 = \beta_2 = \dots = \beta_b = 0$ in the mixed-effects case, the F ratio is MS_β / MS_e . In view of this, it is necessary to know the expected values before we can decide on the appropriate F ratio for testing a hypothesis under mixed- and random-effects models. Fortunately, procedures are available for the easy calculation of the expected values when the data are balanced. The expected values in Table 1 immediately provide us with F ratios for testing all the different hypotheses in the mixed-effects case, as well as in the random-effects case. This is so because, under the hypothesis, we can identify exactly two sums of squares having the same expected value. However, this is not always the case. Sometimes it becomes necessary to use

Table 1 ANOVA and Expected Mean Squares Under Model 3 With Mixed Effects and With Random Effects, When the Data Are Balanced

Source of Variability	Sum of Squares (SS)	Degrees of Freedom	Mean Square (MS)	Expected Mean Square (Mixed-Effects Case)	Expected Mean Square (Random-Effects Case)
Batches	SS	$a - 1$	MS_{τ}	$\sigma_e^2 + bn\sigma_{\tau}^2$	$\sigma_e^2 + n\sigma_{\gamma}^2 + bn\sigma_{\tau}^2$
Operators	SS	$b - 1$	MS_{β}	$\sigma_e^2 + n\sigma_{\gamma}^2 + an \frac{\sum_i \beta_i^2}{b - 1}$	$\sigma_e^2 + n\sigma_{\gamma}^2 + bn\sigma_{\beta}^2$
Interaction	SS°	$(a - 1)(b - 1)$	MS_{γ}	$\sigma_e^2 + n\sigma_{\gamma}^2$	$\sigma_e^2 + n\sigma_{\gamma}^2$
Error	SS_e	$ab(n - 1)$	MS_e	σ_e^2	σ_e^2

a test statistic that is a ratio of the sum of appropriate mean squares, both in the numerator and in the denominator. The test is then carried out using an approximate F distribution. This procedure is known as the *Satterthwaite approximation*.

Analysis of Unbalanced Data

The nice formulas and procedures available for mixed- and random-effects models with balanced data are not available in the case of unbalanced data. While some exact procedures can be derived in the case of a single factor experiment, that is, Model 1, such is not the case when we have a multifactor experiment. One option is to analyze the data with likelihood-based procedures. That is, one can estimate the parameters by maximizing the likelihood and then test the relevant hypotheses with likelihood ratio tests. The computations have to be carried out by available software.

As for estimating the random-effects variances, a point to note is that estimates can be obtained on the basis of either the likelihood or the *restricted likelihood*. Restricted likelihood is free of the fixed-effects parameters. The resulting estimates of the variances are referred to as *restricted maximum likelihood* (REML) estimates. REML estimates are preferred to maximum likelihood estimates because the REML estimates reduce (or eliminate) the bias in the estimates.

Software for Data Analysis Based on Mixed- and Random-Effects Models

Many of the popular statistical software packages can be used for data analysis based on mixed- and random-effects models: R, S-Plus, SAS, SPSS (an IBM company, formerly called PASW Statistics), Stata, and so forth. Their use is rather straight-forward; in fact many

excellent books are now available that illustrate the use of these software packages. A partial list of such books is provided in the Further Readings. These books provide the necessary software codes, along with worked-out examples.

MIXED METHODS DESIGN

Mixed methods is a research orientation that possesses unique purposes and techniques. It integrates techniques from quantitative and qualitative paradigms to tackle research questions that can be best addressed by mixing these two traditional approaches. As long as 40

years ago, scholars noted that quantitative and qualitative research were not antithetical and that every research process, through practical necessity, should include aspects of both quantitative and qualitative methodology. In order to achieve more useful and meaningful results in any study, it is essential to consider the actual needs and purposes of a research problem to determine the methods to be implemented. The literature on mixed methods design is vast, and contributions have been made by scholars from myriad disciplines in the social sciences. Therefore, this entry is grounded in the work of these scholars. This entry provides a historical overview of mixed methods as a paradigm for research, establishes differences between quantitative and qualitative designs, shows how qualitative and quantitative methods can be integrated to address different types of research questions, and illustrates some implications for using mixed methods. Though still new as an approach to research, mixed methods design is expected to soon dominate the social and behavioral sciences.

The objective of social science research is to understand the complexity of human behavior and experience. The task of the researcher, whose role is to describe and explain this complexity, is limited by his or her methodological repertoire. As tradition shows, different methods often are best applied to different kinds of research. Having the opportunity to apply various methods to a single research question can broaden the dimensions and scope of that research and perhaps lead to a more precise and holistic perspective of human behavior and experience. Research is not knowledge itself, but a process in which knowledge is constructed through step-by-step data gathering.

Data are gathered most typically through two distinct classical approaches—qualitative and quantitative. The use of both these approaches for a single study, although sometimes controversial, is becoming more widespread in social science. Methods are really “design” components that include the following: (a) the relationship between the researcher and research “subjects,” (b) details of the experimental environment (place, time, etc.), (c) sampling and data collection methods, (d) data analysis strategies, and (e) knowledge dissemination. The design of a study thus leads to the choice of method strategy. The framework for a study, then, depends on the phenomenon being studied, with the participants and relevant theories informing the research design. Most study designs today need to include both quantitative and qualitative methods for gathering effective data and can thereby incorporate a more expansive set of assumptions and a broader worldview.

Mixing methods (or multiple-methods design) is generally acknowledged as being more pertinent to modern research than using a single approach. Quantitative and qualitative methods may rely more on single data collection methods. For example, whereas a quantitative study may rely on surveys for collecting data, a qualitative study may rely on observations or open-ended questions. However, it is also possible that each of these approaches may use multiple data collection methods. Mixed methods design “triangulates” these two types of methods. When these two methods are used within a single research study, different types of data are combined to answer the research question—a defining feature of mixed methods. This approach is already standard in most major designs. For example, in social sciences, interviews and participant observation form a large part of research and are often combined with other data (e.g., biological markers).

Even though the integration of these two research models is considered fairly novel (emerging significantly in the 1960s), the practice of integrating these two models has a long history. Researchers have often combined these methods, if perhaps only for particular portions of their investigations. Mixed methods research was more common in earlier periods when methods were less specialized and compartmentalized and when there was less orthodoxy in method selection. Researchers observed and cross-tabulated, recognizing that each methodology alone could be inadequate. Synthesis of these two classic approaches in data gathering and interpretation does not necessarily mean that they are wholly combined or that they are uniform. Often they need to be employed separately within a single research design so as not to corrupt either process.

Important factors to consider when one is using mixed methods can be summarized as follows. Mixed methods researchers agree that there are some resonances between the two paradigms that encourage mutual use. The distinctions between these two methods cannot necessarily be reconciled. Indeed, this “tension” can produce more meaningful interactions and thus new results. Combination of qualitative and quantitative methods must be accomplished productively so that the integrity of each approach is not violated: Methodological congruence needs to be maintained so that data collection and analytical strategies are not jeopardized and can be consistent. The two seemingly antithetical research approaches can be productively combined in a pragmatic, interactive, and integrative design model. The two “classical” methods can complement each other and make a study more successful and resourceful by eliminating the possibility of distortion by strict adherence to a single formal theory.

Qualitative and Quantitative Data

Qualitative and quantitative distinctions are grounded in two contrasting approaches to categorizing and explaining data. Different paradigms produce and use different types of data. Early studies distinguished the two methods according to the kind of data collected, whether textual or numerical. The classic qualitative approach includes study of real-life settings, focus on participants' context, inductive generation of theory, open-ended data collection, analytical strategies based on textual data, and use of narrative forms of analysis and presentation. Basically, the qualitative method refers to a research paradigm that addresses interpretation and socially constructed realities. The classic quantitative approach encompasses hypothesis formulation based on precedence, experiment, control groups and variables, comparative analysis, sampling, standardization of data collection, statistics, and the concept of causality. Quantitative design refers to a research paradigm that hypothesizes relationships between variables in an objective way.

Quantitative methods are related to deductivist approaches, positivism, data variance, and factual causation. Qualitative methods include inductive approaches, constructivism, and textual information. In general, quantitative design relies on comparisons of measurements and frequencies across categories and correlations between variables whereas the qualitative method concentrates on events within a context, relying on meaning and process. When the two are used together, data can be transformed. Essentially, "qualitized" data can represent data collected using quantitative methods that are converted into narratives that are analyzed qualitatively. "Quantitized" data represent data collected using qualitative methods that can be converted into numerical codes and analyzed statistically. Many research problems are not linear. Purpose drives the research questions. The course of the study, however, may change as it progresses, leading possibly to different questions and the need to alter method design. As in any rigorous research, mixed methods allows for the research question and purpose to lead the design.

Historical Overview

In the *Handbook of Qualitative Research*, Norman K. Denzin and Yvonna S. Lincoln classified four historic periods in research history for the social sciences. Their classification shows an evolution from strict quantitative methodology, a gradual implementation and acceptance of qualitative methods, to a merging of the two:

(1) traditional (quantitative), 1900 to 1950; (2) modernist, 1950 to 1970; (3) ascendancy of constructivism, 1970 to 1990; and (4) pragmatism and the "compatibility thesis" (discussed later), 1990 to the present.

Quantitative methodology, and its paradigm, positivism, dominated methodological orientation during the first half of the 20th century. This "traditional" period, although primarily focused on quantitative methods, did include some mixed method approaches without directly acknowledging implementation of qualitative data: Studies often made extensive use of interviews and researcher observations, as demonstrated in the *Hawthorne effect*. In the natural sciences, such as biology, paleontology, and geology, goals and methods that typically would be considered qualitative (naturalistic settings, inductive approaches, narrative description, and focus on context and single cases) have been integrated with those that were regarded as quantitative (experimental manipulation, controls and variables, hypothesis testing, theory verification, and measurement and analysis of samples) for more than a century.

After World War II, positivism began to be discredited, which led to its "intellectual" successor, postpositivism. Postpositivism (still largely in the domain of the quantitative method) asserts that research data are influenced by the values of the researchers, the theories used by the researchers, and the researchers' individually constructed realities. During this period, some of the first explicit mixed method designs began to emerge. While there was no distinctive categorization of mixed methods, numerous studies began to employ components of its design, especially in the human sciences. Data obtained from participant observation (qualitative information) was often implemented, for example, to explain quantitative results from a field experiment.

The subsequent "modernist" period, or "Golden Age" (1950–1970), has been demarcated, then, by two trends: positivism's losing its stronghold and research methods that began to incorporate "multi methods." The discrediting of positivism resulted in methods that were more radical than those of postpositivism. From 1970 to 1985—defined by some scholars as the "qualitative revolution"—qualitative researchers became more vocal in their criticisms of pure quantitative approaches and proposed new methods associated with constructivism, which began to gain wider acceptance. In the years from 1970 to 1990, qualitative methods, along with mixed method syntheses, were becoming more eminent. In the 1970s, the combination of data sources and multiple methods was becoming more fashionable, and new paradigms, such as interpretivism and naturalism, were gaining precedence and validity.

In defense of a “paradigm of purity,” a period known as the *paradigm wars* took place. Different philosophical camps held that quantitative and qualitative methods could not be combined; such a “blending” would corrupt accurate scientific research. Compatibility between quantitative and qualitative methods, according to these proponents of quantitative methods, was impossible due to the distinction of the paradigms. Researchers who combined these methods were doomed to fail because of the inherent differences in the underlying systems. Qualitative researchers defined such “purist” traditions as being based on “received” paradigms (paradigms preexisting a study that are automatically accepted as givens), and they argued against the prejudices and restrictions of positivism and postpositivism. They maintained that mixed methods were already being employed in numerous studies.

The period of pragmatism and compatibility (1990–the present) as defined by Denzin and Lincoln constitutes the establishment of mixed methods as a separate field. Mixed methodologists are not representative of either the traditional (quantitative) or “revolutionary” (qualitative) camps. In order to validate this new field, mixed methodologists had to show a link between epistemology and method and demonstrate that quantitative and qualitative methods were compatible. One of the main concerns in mixing methods was to determine whether it was also viable to mix paradigms—a concept that circumscribes an interface, in practice, between epistemology (historically learned assumptions) and methodology. A new paradigm, pragmatism, effectively combines these two approaches and allows researchers to implement them in a complementary way.

Pragmatism addresses the philosophical aspect of a paradigm by concentrating on what works. Paradigms, under pragmatism, do not represent the primary organizing principle for mixed methods practice. Believing that paradigms (socially constructed) are malleable assumptions that change through history, pragmatists make design decisions based on what is practical, contextually compatible, and consequential. Decisions about methodology are not based solely on congruence with established philosophical assumptions but are founded on a methodology’s ability to further the particular research questions within a specified context. Because of the complexity of most contexts under research, pragmatists incorporate a dual focus between sense making and value making. Pragmatic research decisions, grounded in the actual context being studied, lead to a logical design of inquiry that has been termed *fitness for purpose*. Mixed methodologies are the result. Pragmatism demonstrates that singular paradigm beliefs are not intrinsically connected to specific

methodologies; rather, methods and techniques are developed from multiple paradigms.

Researchers began to believe that the concept of a single best paradigm was a relic of the past and that multiple, diverse perspectives were critical to addressing the complexity of a pluralistic society. They proposed what they defined as the *dialectical* stance: Opposing views (paradigms) are valid and provide for more realistic interaction. Multiple paradigms, then, are considered a foundation for mixed methods research. Researchers, therefore, need to determine which paradigms are best for a particular mixed methods design for a specific study.

Currently, researchers in social and behavioral studies generally comprise three groups: Quantitatively oriented researchers, primarily interested in numerical and statistical analyses; qualitatively oriented researchers, primarily interested in analysis of narrative data; and mixed methodologists, who are interested in working with both quantitative and qualitative data. The differences between the three groups (particularly between quantitatively and qualitatively oriented researchers) have often been characterized as the paradigm wars. These three movements continue to evolve simultaneously, and all three have been practiced concurrently. Mixed methodology is in its adolescent stage as scholars work to determine how to best integrate different methods.

Integrated Design Models

A. Tashakkori and C. Teddlie have referred to three categories of multiple-method designs: multimethod research, mixed methods research, and mixed model research. The terms *multimethod* and *mixed method* are often confused, but they actually refer to different processes. In multimethod studies, research questions use both quantitative and qualitative procedures, but the process is applied principally to quantitative studies. This method is most often implemented in an inter-related series of projects whose research questions are theoretically driven. Multimethod research is essentially complete in itself and uses simultaneous and sequential designs.

Mixed methods studies, the primary concern of this entry, encompass both mixed methods and mixed model designs. This type of research implements qualitative and quantitative data collection and analysis techniques in parallel phases or sequentially. Mixed methods (combined methods) are distinguished from mixed model designs (combined quantitative and qualitative methods in all phases of the research). In mixed methods design, the “mixing” occurs in the type of questions asked and in the inferences that evolve.

Mixed model research is implemented in all stages of the study (questions, methods, data collection, analysis, and inferences).

The predominant approach to mixing methods encompasses two basic types of design: *component* and *integrated*. In component designs, methods remain distinct and are used for discrete aspects of the research. Integrative design incorporates substantial integration of methods. Although typologies help researchers organize actual use of both methods, use of typologies as an organizing tool demonstrates a lingering linear concept that refers more to the duality of quantitative and qualitative methods than to the recognition and implementation of multiple paradigms. Design components (based on objectives, frameworks, questions, and validity strategies), when organized by typology, are perceived as separate entities rather than as interactive parts of a whole. This kind of typology illustrates a pluralism that “combines” methods without actually integrating them.

Triangulation and Validity

Triangulation is a method that combines different theoretical perspectives within a single study. As applied to mixed methods, triangulation determines an unknown point from two or more known points, that is, collection of data from different sources, which improves validity of results. In *The Research Act*, Denzin argued that a hypothesis explored under various methods is more valid than one tested under only one method. Triangulation in methods, where differing processes are implemented, maximizes the validity of the research: Convergence of results from different measurements enhances validity and verification. It was also argued that using different methods, and possibly a faulty commonality of framework, could lead to increased error in results. Triangulation may not increase validity but does increase consistency in methodology: Though empirical results may be conflicting, they are not inherently damaging but render a more holistic picture.

Triangulation allows for the exploration of both theoretical and empirical observation (inductive and deductive), two distinct types of knowledge that can be implemented as a methodological “map” and are logically connected. A researcher can structure a logical study, and the tools needed for organizing and analyzing data, only if the theoretical framework is established prior to empirical observations. Triangulation often leads to a situation in which different findings do not converge or complement each other. Divergence of results, however, may lead to additional valid explanations of the study. Divergence, in this case, can be

reflective of a logical reconciliation of quantitative and qualitative methods. It can lead to a productive process in which initial concepts need to be modified and adapted to differing study results.

Recently, two new approaches for mixing methods have been introduced: an *interactive* approach, in which the design components are integrated and mutually influence each other, and a *conceptual* approach, using an analysis of the fundamental differences between quantitative and qualitative research. The interactive method, as employed in architecture, engineering, and art, is neither linear nor cyclic. It is a schematic method that addresses data in a mutually ongoing arrangement. This design model is a tool that focuses on analyzing the research question rather than providing a template for creating a study type. This more qualitative approach to mixed methods design emphasizes particularity, context, comprehensiveness, and the process by which a particular combination of qualitative and quantitative components develops in practice, in contrast to the categorization and comparison of data typical of the pure quantitative approach.

Implications for Mixed Methods

As the body of research regarding the role of the environment and its impact on the individual has developed, the status and acceptance of mixed methods research in many of the applied disciplines is accelerating. This acceptance has been influenced by the historical development of these disciplines and an acknowledgment of a desire to move away from traditional paradigms of positivism and postpositivism. The key contributions of mixed methods have been to an understanding of individual factors that contribute to social outcomes, the study of social determinants of medical and social problems, the study of service utilization and delivery, and translational research into meaningful practice.

Mixed methods research may bridge postmodern critiques of scientific inquiry and the growing interest in qualitative research. Mixed methods research provides an opportunity to test research questions, hypotheses, and theory and to acknowledge the phenomena of human experience. Quantitative methods support the ability to generalize findings to the general population. However, quantitative approaches that are well regarded by researchers may not necessarily be comprehensible or useful to lay individuals. Qualitative approaches can help contextualize problems in narrative forms and thus can be more meaningful to lay individuals. Mixing these two methods offers the potential for researchers to understand, contextualize, and develop interventions.

Mixed methods have been used to examine and implement a wide range of research topics, including instrument design, validation of constructs, the relationship of constructs, and theory development or disconfirmation. Mixed methods are rooted, for one example, in the framework of feminist approaches whereby the study of participants' lives and personal interpretations of their lives has implications in research. In terms of data analysis, content analysis is a way for scientists to confirm hypotheses and to gather qualitative data from study participants through different methods (e.g., grounded theory, phenomenological, narrative). The application of triangulation methodology is extremely invaluable in mixed methods research.

While there are certainly advantages to employing mixed methods in research, their use also presents significant challenges. Perhaps the most significant issue to consider is the amount of time associated with the design and implementation of mixed methods. In addition to time restrictions, costs or barriers to obtaining funding to carry out mixed methods research are a consideration.

Conclusion

Rather than choosing one paradigm or method over another, researchers often use multiple and mixed methods. Implementing these newer combinations of methods better supports the modern complexities of social behavior the changing perceptions of reality and knowledge better serve the purposes of the framework of new studies in social science research. The classic quantitative and qualitative models alone cannot encompass the interplay between theoretical and empirical knowledge. Simply, combining methods makes common sense and serves the purposes of complex analyses. Methodological strategies are tools for inquiry and represent collections of strategies that corroborate a particular perspective. The strength of mixed methods is that research can evolve comprehensively and adapt to empirical changes, thus going beyond the traditional dualism of quantitative and qualitative methods, redefining and reflecting the nature of social reality.

Paradigms are social constructions, culturally and historically embedded as discourse practices, and contain their own set of assumptions. As social constructions, paradigms are changeable and dynamic. The complexity and pluralism of our contemporary world require rejecting investigative constraints of singular methods and implementing more diverse and integrative methods that can better address research questions and evolving social constructions. Knowledge and information change with time and mirror evolving social perceptions and needs. Newer paradigms and

belief systems can help transcend and expand old dualisms and contribute to redefining the nature of social reality and knowledge.

Scholars generally agree that it is possible to use qualitative and quantitative methods to answer objective–value and subjective–constructivist questions, to include both inductive–exploratory and deductive–confirmatory questions in a single study, to mix different orientations, and to integrate qualitative and quantitative data in one or more stages of research, and that many research questions can only be answered with a mixed methods design. Traditional approaches meant aligning oneself to either quantitative or qualitative methods. Modern scholars believe that if research is to go forward, this dichotomy needs to be fully reconciled.

MIXED MODEL DESIGN

Mixed model designs are an extension of the general linear model, as in analysis of variance (ANOVA) designs. There is no common term for the mixed model design. Researchers sometimes refer to *split-plot designs*, *randomized complete block*, *nested*, *two-way mixed ANOVAs*, and certain repeated measures designs as mixed models. Also, mixed model designs may be restrictive or nonrestrictive. The restrictive model is used most often because it is more general, thus allowing for broader applications. A mixed model may be thought of as two models in one: a *fixed-effects model* and a *random-effects model*. Regardless of the name,

statisticians generally agree that when interest is in both fixed and random effects, the design may be classified as a mixed model. Mixed model analyses are used to study research problems in a broad array of fields, ranging from education to agriculture, sociology, psychology, biology, manufacturing, and economics.

Purpose of the Test

A mixed model analysis is appropriate if one is interested in a between-subjects effect (fixed effect) in addition to within-subjects effects (random effects), or in exploring alternative covariance structures on which to model data with between- and within-subjects effects. A variable may be fixed or random. Random effects allow the researcher to generalize beyond the sample.

Fixed and random effects are a major feature distinguishing the mixed model from the standard repeated measures design. The standard two-way repeated measures design examines repeated measures on the same subjects. These are within-subjects designs for two factors with two or more levels. In the two-way mixed model design, two factors, one for within-subjects and one for between-subjects are always included in the model. Each factor has two or more levels. For example, in a study to determine the preferred time of day for undergraduate and graduate college students to exercise at a gym, time of day would be a within-subjects factor with three levels: 5:00 a.m., 1:00 p.m., and 9:00 p.m.; and student classification as undergraduate or graduate would be two levels of a between-subjects factor. The dependent variable for such a study could be a score on a workout preference scale. A design with three levels on a random factor and two levels on a fixed factor is written as a 2×3 mixed model design.

Fixed and Random Effects

Fixed Effects

Fixed effects, also known as between-subjects effects, are those in which each subject is a member of either one group or another, but not more than one group. All levels of the factor may be included, or only selected levels. In other words, subjects are measured on only one of the designated levels of the factor, such as undergraduate or graduate. Other examples of fixed effects are gender, membership in a control group or an experimental group, marital status, and religious affiliation.

Random Effects

Random effects, also known as within-subjects effects, are those in which measures of each level of a

factor are taken on each subject, and the effects may vary from one measure to another over the levels of the factor. Variability in the dependent variable can be attributed to differences in the random factor. In the previous example, all subjects would be measured across all levels of the time-of-day factor for exercising at a gym. In a study in which time is a random effect and gender is a fixed effect, the interaction of time and gender is also a random effect. Other examples of random effects are number of trials, in which each subject experiences each trial or each subject receives repeated doses of medication. Random effects are the measures from the repeated trials, measures after the time intervals of some activities, or repeated measures of some function such as blood pressure, strength level, endurance, or achievement. The mixed model design may be applied when the sample comprises large units, such as school districts, military bases, and universities, and the variability among the units, rather than the differences in means, is of interest. Examining random effects allows researchers to make inferences to a larger population.

Assumptions

As with other inferential statistical procedures, the data for a mixed model analysis must meet certain statistical assumptions if trustworthy generalizations are to be made from the sample to the larger population. Assumptions apply to both the between- and within-subjects effects. The between-subjects assumptions are the same as those in a standard ANOVA: independence of scores; normality; and equal variances, known as *homogeneity of variance*. Assumptions for the within-subjects effects are independence of scores and normality of the distribution of scores in the larger population. The mixed model also assumes that there is a linear relationship between the dependent and independent variables. In addition, the complexity of the mixed model design requires the assumption of equality of variances of the difference scores for all pairs of scores at all levels of the within-subjects factor and equal covariances for the between-subjects factor. This assumption is known as the *sphericity assumption*. Sphericity is especially important to the mixed model analysis.

Sphericity Assumption

The sphericity assumption may be thought of as the homogeneity-of-variance assumption for repeated measures. This assumption can be tested by conducting correlations between and among all levels of repeated measures factors and using Bartlett's test of sphericity. A significant probability level (p value) means that the data are correlated and the sphericity assumption is

violated. However, if the data are uncorrelated, then sphericity can be assumed. Multivariate ANOVA (MANOVA) procedures do not require that the sphericity assumption be met; consequently, statisticians suggest using the MANOVA results rather than those in the standard repeated measures analysis.

Mixed model designs can accommodate complex covariance patterns for repeated measures with three or more levels on a factor, eliminating the need to make adjustments. Many different variance–covariance structures are available for fitting data to a mixed model design. Most statistical software can invoke the mixed model design and produce parameter estimates and tests of significance.

Variance–Covariance Structures

Relationships between levels of the repeated measures are specified in a covariance structure. Several different covariance structures are available from which to choose. The variance–covariance structure of a data set is helpful to determine whether the data fit a specific model. A few of the most common covariance structures are introduced in the following paragraphs.

Diagonal, or Variance, Components Structure

The diagonal, or variance, components structure is the simplest of the covariance patterns. This model, characterized by 1s on the diagonal and 0s on the off-diagonals, is also known as the *identity matrix*. The variance components pattern displays constant variance and no correlation between the elements. This is an unsatisfactory covariance structure for a mixed model design with repeated measures because the measures from the same subject are not independent.

Compound Symmetry

Compound symmetry displays a covariance pattern among the multiple levels of a single factor in which all the off-diagonal elements are constant (equal) and all diagonal elements are constant (equal) regardless of the time lapse between measurements; thus such a pattern of equal variances and covariances indicates that the sphericity assumption is satisfied. The compound symmetry structure is a special case of the simple variance component model that assumes independent measures and homogeneous variance.

First-Order Autoregressive Structure

The first-order autoregressive structure, or AR(1), model is useful when there are evenly spaced time intervals between the measurements. The covariance between

any two levels is a function of the spacing between the measures. The closer the measurements are in time, the higher will be the correlations between adjacent measures. The AR(1) pattern displays a homogeneous structure, with equal variances and covariances that decrease exponentially as the time between measures increases. For example, this exponential function can be seen when an initial measure is taken and repeated at 1 year, 2 years, 3 years, and so forth. Smaller correlations will be observed for observations separated by 3 years than for those separated by 2 years. The model consists of a parameter for the variance of the observations and a parameter for the correlation between adjacent observations. The AR(1) is a special case of the Toeplitz, as discussed later in this entry.

Unstructured Covariance Structure

The variances for each level of a repeated measures factor and the covariances in an unstructured variance–covariance matrix are all different. The unstructured covariance structure (UN), also known as a *general covariance structure*, is the most heterogeneous of the covariance structures. The UN possibly offers the best fit because every covariance entry can be unique. However, this heterogeneity introduces more complexity in the model and more parameters to be estimated. Unlike the first-order autoregressive structure that produces two parameters, the UN pattern requires parameters equal to $n(n + 1)/2$, where n is the number of repeated measures for a factor. For example, 10 parameters are estimated for four repeated measures: $4(4 + 1)/2 = 10$.

Toeplitz Covariance Structure

In the Toeplitz covariance model, correlations at the same distance are the same as in the AR(1) model; however, there is no exponential effect. The number of parameters depends on the number of distances between measures. For example, the distance between the initial measure and the second measure would be one parameter; the distance between the second measure and the third measure would be another parameter, and so forth. Like the AR(1) model, the Toeplitz is a suitable choice for evenly spaced measures.

First Order: Ante-Dependence

The first-order ante-dependence model is a more general model than the Toeplitz or the AR(1) models. Covariances are dependent on the product of the variances at the two points of interest, and correlations are weighted by the variances of the two points of interest.

For example, a correlation of .70 for points 1 and 2 and a correlation of .20 for points 2 and 3 would produce a correlation of .14 for points 1 and 3. This model requires $2n - 1$ parameters to be estimated, where n is the number of repeated measures for a factor.

Evaluating Covariance Models

The data should be examined prior to the analysis to verify whether the mixed model design or the standard repeated measures design is the appropriate procedure. Assuming that the mixed model procedure is appropriate for the data, the next step is to select the covariance structure that best models the data. The sphericity test alone is not an adequate criterion by which to select a model. A comparison of information criteria for several probable models with different covariance structures that uses the maximum likelihood and restricted maximum likelihood estimation methods is helpful in selecting the best model.

One procedure for evaluating a covariance structure involves creating a mixed model with an unstructured covariance matrix and examining graphs of the error covariance and correlation matrices. Using the residuals, the error covariances or correlations can be plotted separately for each start time, as in a trend analysis. For example, declining correlations or covariances with increasing time lapses between measures indicate that an AR(1) or ante-dependence structure is appropriate. For trend analysis, trends with the same mean have approximately the same variance. This pattern can also be observed on a graph with lines showing multiple trends. If the means or the lines on the graph are markedly different and the lines do not overlap, a covariance structure that accommodates variance heterogeneity is appropriate.

Another procedure for evaluating a covariance matrix involves creating several different probable models using both the maximum likelihood and the restricted maximum likelihood methods of parameter estimation. The objective is to select the covariance structure that gives the best fit of the data to the model. Information criterion measures, produced as part of the results of each mixed model procedure, indicate a relative goodness of fit of the data, thus providing guidance in model evaluation and selection. The information criteria measures for the same data set under different models (different covariance structures) and estimated with different methods can be compared; usually, the information criterion with the smallest value indicates a better fit of the data to the model. Several different criterion measures can be produced as part of the statistical analysis. It is not uncommon for the information criteria measures to be very close in value.

Hypothesis Testing

The number of null hypotheses formulated for a mixed model design depends on the number of factors in the study. A null hypothesis should be generated for each factor and for every combination of factors. A mixed model analysis with one fixed effect and one random effect generates three null hypotheses. One null hypothesis would be stated for the fixed effects; another null hypothesis would be stated for the random effects; and a third hypothesis would be stated for the interaction of the fixed and random effects. If more than one fixed or random factor is included, multiple interactions may be of interest. The mixed model design allows researchers to select only the interactions in which they are interested.

The omnibus F test is used to test each null hypothesis for mean differences across levels of the main effects and interaction effects. The sample means for each factor main effect are compared to ascertain whether the difference between the means can be attributed to the factor rather than to chance. Interaction effects are tested to ascertain whether a difference between the means of the fixed effects between subjects and the means of each level of the random effects within subjects is significantly different from zero. In other words, the data are examined to ascertain the extent to which changes in one factor are observed across levels of the other factor.

Interpretation of Results

Several tables of computer output are produced for a mixed model design. The tables allow researchers to check the fit of the data to the model selected and interpret results for the null hypotheses.

Model Dimension Table

A model dimension table shows the fixed and random effects and the number of levels for each, type of covariance structure selected, and the number of parameters estimated. For example, AR(1) and compound symmetry covariance matrices estimate two parameters whereas the number of parameters varies for a UN based on the number of repeated measures for a factor.

Information Criteria Table

Goodness-of-fit statistics are displayed in an information criteria table. Information criteria can be compared when different covariance structures and/or estimation methods are specified for the model. The tables resulting from different models can be used to

compare one model with another. Information criteria are interpreted such that a smaller value means a better fit of the data to the model.

Fixed Effects, Random Effects, and Interaction Effects

Parameter estimates for the fixed, random, and interaction effects are presented in separate tables. Results of the fixed effects allow the researcher to reject or retain the null hypothesis of no relationship between the fixed factors and the dependent variable. The level of significance (p value) for each fixed effect will indicate the extent to which the fixed factor or factors have an effect different from zero on the dependent variable.

A table of estimates of covariance parameters indicates the extent to which random factors have an effect on the dependent variable. Random effects are reported as variance estimates. The level of significance allows the researcher to reject or retain the null hypothesis that the variance of the random effect is zero in the population. A nonsignificant random effect can be dropped from the model, and the analysis can be repeated with one or more other random effects.

Interaction effects between the fixed and random effects are also included as variance estimates. Interaction effects are interpreted on the basis of their levels of significance. For all effects, if the 95% confidence interval contains zero, the respective effects are nonsignificant. The residual parameter estimates the unexplained variance in the dependent variable after controlling for fixed effects, random effects, and interaction effects.

Advantages

The advantages of the mixed model compensate for the complexity of the design. A major advantage is that the requirement of independence of individual observations does not need to be met as in the general linear model or regression procedures. The groups formed for higher-level analysis such as in nested designs and repeated measures are assumed to be independent; that is, they are assumed to have similar covariance structures. In the mixed model design, a wide variety of covariance structures may be specified, thus enabling the researcher to select the covariance structure that provides the model of best fit. Equal numbers of repeated observations for each subject are not required, making the mixed model design desirable for balanced and unbalanced designs. Measures for all subjects need not be taken at the same points in time. All existing data are incorporated into the analysis even though

there may be missing data points for some cases. Finally, mixed model designs, unlike general linear models, can be applied to data at a lower level that are contained (nested) within a higher level, as in hierarchical linear models.

MIXTURE MODELS

Mixture models were created to decompose nonnormal univariate or multivariate distributions into distinct (i.e., a mixture of) normal distributions. In the social sciences, mixture models are typically referred to as *person-centered* analyses and used to identify distinct subpopulations of participants, referred to as *profiles*, differing from one another quantitatively and qualitatively on a series of indicators and/or relations among indicators. Quantitative research typically relies on statistics (e.g., correlations, regressions) obtained from a sample to infer what happens in the population from which the sample was extracted. Mixture models relax this assumption of population homogeneity (i.e., that

the results can be generalized to all members of the population) to extract subpopulations (i.e., profiles) characterized by a distinct set of results. After briefly reviewing the history of mixture models, this entry describes the defining characteristics of these models, discusses several types of mixture models, and examines the main current limitations of these models.

History

Mixture models have been around since the end of the 1950s, although early developments can be traced back to Karl Pearson in 1894. The estimation of these models was greatly simplified in the late 1970s with the development of the expectation-maximization algorithm. However, the popularity of these models increased since the beginning of the 21st century following the development of user-friendly statistical packages (Mplus, Latent Gold, Stata-GLLMM, and SAS-ProcTraj) and the creation of connections between mixture models and the structural equation modeling (SEM) framework. The resulting statistical framework is referred to as generalized SEM (GSEM).

Defining Characteristics of the GSEM Framework

The GSEM framework allows researchers to study relations occurring among any number of observed or latent continuous or categorical variables and to decompose these relations across different levels of analysis (e.g., occasions, individual, group). In SEM, a latent variable is used to infer the presence of unobservable constructs (e.g., self-esteem) from a series of indicators (e.g., responses to a questionnaire). These latent variables are corrected for the imprecise nature (i.e., random measurement error) of the indicators, resulting in the ability to estimate relations among latent variables corrected for unreliability. GSEM adds to SEM the ability to estimate categorical latent variables, reflecting latent (unobserved) subpopulations (profiles) differing from one another on any, or all, parts of a SEM model. These profiles present three defining characteristics.

Typological

Latent profiles are typological, resulting in a classification system whereby participants are assumed to come from distinct subpopulations characterized by a distinct set of results. This classification ability is an important advantage of person-centered analyses given its alignment with humans' natural tendency to think in terms of categories.

Prototypical

Latent profiles are prototypical, resulting in a classification system whereby each participant is assigned a probability of membership into all profiles. This probability reflects the degree of similarity between the participant and the latent prototypes reflected by the profiles. Just as SEM decomposes observed variance into latent factors corrected from measurement error and unique components incorporating this error, this prototypical nature results in profiles corrected for classification error.

Exploratory

SEM typically involves the estimation of an a priori model, matching theoretical expectations, which is assessed in terms of model fit information, and can be contrasted with other a priori models. Mixture models involve a more exploratory, or inductive, process. In mixture models, the optimal solution is typically selected after consideration of alternative solutions including increasing numbers of profiles, which are then contrasted on various statistical indicators and in terms of theoretical, heuristic, and practical meaningfulness. For this reason, providing evidence of replicability (over groups or time points) and construct validity (in terms of associations with predictors or outcomes) is critical to the demonstration of the meaningfulness of a solution. This inductive nature does not mean that mixture models cannot be used for confirmatory (deductive) purposes. Any exploratory *method* can be used for confirmatory or exploratory *purposes*. However, confirmatory applications of mixture models are also available for research areas where theory and research are sufficient to support a priori hypotheses. Yet, even then, the a priori model would have to be contrasted with unconstrained models to document its value following a more exploratory methodology.

Main Models

The following paragraphs describe the main types of mixture models that can be estimated in the GSEM framework.

Latent Profile Analysis (LPA) and Latent Class Analysis (LCA)

LPA (continuous indicators) or LCA (categorical indicators) identifies profiles of participants characterized by a qualitatively and quantitatively distinct configuration on a series of indicators. For instance, motivational profiles could reveal participants

presenting a profile dominated by intrinsic types of motivation, another profile dominated by extrinsic types of motivations, and a third profile characterized by both types of motivations.

Factor Mixture Analysis (FMA)

FMA combines factor analyses and LPA/LCA. FMA can be used to (a) implement a continuous factor to control for shared tendencies among profile indicators; (b) identify subpopulations characterized by differential item functioning on a factor model; (c) analyze the underlying continuous, categorical, or hybrid nature of latent constructs (e.g., does suffering from major depression really mean that one falls into a distinct category of persons? Is depression better reflected along a continuum of severity? Or a combination of both?).

Mixture Regression Analysis (MRA)

MRA seeks to identify subpopulations characterized by a distinct pattern of association (i.e., regressions intercepts, slopes, and residuals) between latent or observed variables. Two types of models have to be distinguished from MRA. First, profiles defined according to LPA/LCA can be used as moderators of relations between other variables. In this approach, a series of indicators (p) are used to define the latent profiles. Then, relations between predictor (x) and outcome (y) variables are estimated in each latent profile. In contrast, in MRA, only the x - y relations are used to define the profiles, with no additional indicator (p) used in profile definition. Second, a hybrid approach combines LPA/LCA and MRA to define profiles from a specific configuration on a set of indicators (p) and from the relations between these indicators and outcomes (p - y relations).

Latent Transition Analysis (LTA)

LTA estimates associations between two or more latent categorical variables: Membership into one set of profiles is used to predict membership into a second set of profiles. As such, LTA can provide a connection between any type of mixture models (e.g., between LPA and MRA) within, or across, time points. Despite this broad capability, LTA is typically applied to estimate longitudinal transitions in profile membership (i.e., within-person stability) occurring among similarly defined profiles.

Growth Mixture Analysis (GMA)

GMA is an extension of latent curve (or latent growth) models (LCM) in which profiles reflect

subpopulations characterized by different trajectories on a set of repeated measures. As in LCM, various functional specifications can be used to define modeling trajectories (e.g., linear, quadratic, latent basis, exponential). Although the same functional form is imposed in all profiles, variations in model parameters can result in profiles presenting qualitatively distinct trajectories. For example, a quadratic GMA could result in one profile displaying a stable trajectory, a second displaying a U-shape trajectory, and a third displaying a linear decrease.

Multilevel Mixture Analysis

In multilevel mixture analysis, latent profiles could be defined from the same, or even from distinct, indicators across levels (i.e., occasion, person, group). In the most common form of multilevel mixture model, profiles are estimated at the first level (typically the individual) and profile membership is allowed to differ across higher level units (e.g., classroom, schools, work groups). Profiles can also directly be estimated at this higher level of analyses and defined either as a function of the relative frequency of occurrence of lower level profiles or from the same set of indicators aggregated at the higher level.

Tests of Profile Similarity

In SEM, tests of measurement and predictive invariance can be used to quantitatively test the extent to which model parameters generalize across subgroups (e.g., males or females) of participants or over time. Likewise, tests of profile similarity can be used to assess the extent to which the number, shape, within-profile variability, size, regressions (in MRA), and even relations with covariates generalize across subgroups of participants or time points. Currently, procedures have been proposed to guide tests of profile similarity for LPA, LCA, MRA, LTA, and multilevel mixture models.

Predictors and Outcomes

Currently, the main advantage of mixture models over other classification methods (such as cluster analytic procedures) comes from their incorporation into GSEM. This incorporation makes it possible to extend them to multiple time points or groups but also to link the resulting profiles to any number of predictors or outcomes, providing a way to assess in single-step predictive associations among observed and latent categorical and continuous variables corrected for measurement and classification errors.

One caveat remains, however: Including these covariates should not modify the nature of the profiles. Covariates should thus be incorporated to the final unconditional solution and not allowed to influence the profile estimation procedure (technically, means using the parameter estimates from the unconditional solution as freed or fixed start values rather than relying on random starts). However, even then, changes might happen.

A variety of *auxiliary* approaches have been proposed to address this issue. Interestingly, the manual implementation of some of these approaches provides a way to introduce additional flexibility to mixture models, making it possible to use profiles as moderators, to integrate profiles in tests of mediation, to implement tests of profile similarity in LTA or multi-level models, or to use profiles as the grouping variable in analysis of covariance—like mean comparisons.

Current Limitations of GSEM

As part of GSEM, mixture models are very flexible (i.e., various parameters can be allowed to differ, or not, across profiles). This does not mean that they are without limitations. Apart from their complexity, one of those limitations comes from their computationally intensive nature, which means that their estimation requires much more computational time than most other types of models. This complexity also means that despite the existence of extensive connections between mixture modeling and SEM, some of those connections still frequently fail to converge on proper solutions. For instance, many attempts to estimate LPA or MRA on the basis of latent factors tend to result in nonconverging solutions. Current recommendations are thus to start any study by a cautious investigation of the measurement properties of all variables and to rely on factor scores (allowing for a partial correction of measurement error) saved from these models as profile indicators. Another consequence of this complexity is that mixture models require larger samples than typical SEM applications in order to ensure convergence on proper solutions and to allow for the identification of small profiles as part of relatively stable solutions. Finally, person-centered evidence is known to be cumulative in nature, requiring an accumulation of studies to differentiate the core set of profiles that systematically emerge, from the situation-specific profiles and from those simply reflecting random sampling variations. Unfortunately, guidelines on the best way to quantitatively combine person-centered results (i.e., meta-analytic approaches) are still lacking.

MODE

Together with the mean and the median, the mode is one of the main measurements of the central tendency of a sample or a population. The mode is particularly important in social research because it is the only measure of central tendency that is relevant for any data set. That being said, it rarely receives a great deal of attention in statistics courses. The purpose of this entry is to identify the role of the mode in relation to the median and the mean for summarizing various types of data.

Definition

The mode is generally defined as the most frequent observation or element in the distribution. Unlike the mean and the median, there can be more than one mode. A sample or a population with one mode is unimodal. One with two modes is bimodal, one with three modes is trimodal, and so forth. In general, if there is more than one mode, one can say that a sample or a distribution is multimodal.

History

The mode is an unusual statistic among those defined in the field of statistics and probability. It is a counting term, and the concept of counting elements in categories dates back prior to human civilization. Recognizing the maximum of a category, be it the maximum number of predators, the maximum number of food sources, and so forth, is evolutionarily advantageous.

The mathematician Karl Pearson is often cited as the first person to use the concept of the mode in a statistical context. Pearson, however, also used a number of other descriptors for the concept, including the “maximum of theory” and the “ordinate of maximum frequency.”

Calculation

In order to calculate the mode of a distribution, it is helpful first to group the data into like categories and to determine the frequency of each observation. For small samples, it is often easy to find the mode by looking at the results. For example, if one were to roll a die 12 times and get the following results,

{1, 3, 2, 4, 6, 3, 4, 3, 5, 2, 5, 6},

it is fairly easy to see that the mode is 3.

However, if one were to roll the die 40 times and list the results, the mode is less obvious:

{6, 5, 5, 4, 4, 1, 6, 6, 3, 4, 4, 4, 2, 5,
5, 4, 4, 1, 2, 1, 4, 5, 5, 1, 3, 5, 2, 4,
2, 4, 2, 4, 4, 6, 5, 2, 1, 1, 4, 5}.

In Table 1, the data are grouped by frequency, making it obvious that the mode is 4.

Often, a statistician will be faced with a table of frequencies in which the individual data have been grouped into ranges of categories. Table 2 gives an example of such a table. We can see that the category of incomes between \$40,000 and \$60,000 has the largest number of members. We can call this the modal class. Yadolah Dodge has outlined a method for

Table 1 Data of Frequency of Die Rolled 40 Times

<i>Number</i>	<i>Observations</i>
1	6
2	6
3	2
4	13
5	9
6	4

Table 2 Frequencies in Which Individual Data Are Grouped Into Ranges of Categories

<i>Classes (income by categories)</i>	<i>Frequencies (number in each category)</i>
0–\$20k	12
\$20k–\$40k	23
\$60k–\$60k	42
\$60k–\$80k	25
\$80k–\$100k	9
\$100k–\$120k	2
Total	113

calculating a more precise estimate for the mode in such circumstances:

$$\text{mode} = L_1 + \left(\frac{d_1}{d_1 + d_2} \right) \times c,$$

where L_1 = lower value of the modal category; d_1 = difference between the number in the modal class and the class below; d_2 = difference between the number in the modal class and the class above; and c = length of the interval within the modal class. (This interval length should be common for all intervals.)

In this particular example, the mode would be

$$\text{mode} = \$40,000 + \left(\frac{19}{19 + 17} \right) \times \$20,000.$$

Therefore, the mode would be estimated to be \$50,556.

The Mode for Various Types of Data Classification

Discrete and Continuous Data

In mathematical statistics, distributions of data are often discussed under the heading of discrete or continuous distributions. As the previous examples have

Figure 1 Example of Modes for Continuous Distributions

shown, computing the mode is relatively straightforward with discrete data, although some organizing of the data may be necessary.

For continuous data, the concept of mode is less obvious. No value occurs more than once in continuous probability distributions, and therefore, no single value can be defined as the mode with the discrete definition. Instead, for continuous distributions, the mode occurs at a local maximum in the data. For example, in Figure 1, the modes occur at 5 and 15.

As Figure 1 shows, for continuous distributions, a distribution can be defined as multimodal even when the local maximum at 5 is greater than the local maximum at 15.

The Stevens Classification System

In social science statistical courses, data are often classified according to data scales outlined by Stanley Smith Stevens.

According to Stevens's classification system, data can be identified as nominal, ordinal, interval, or ratio. As Stevens points out, the mode is the only measure of central tendency applicable to all data scales.

Data that comply with *ratio scales* can be either continuous or discrete and are amenable to all forms of statistical analysis. In mathematical terms, data can be drawn from the real, integer, or natural number systems. Although the mode applies as a measure of central tendency for such data, it is not usually the most useful measurement of central tendency. An example of ratio-scale data would be the total net worth of a randomly selected sample of individuals. So much variability is possible in the possible outcomes that unless the data are grouped into discrete categories (say increments of \$5,000 or \$10,000) the mode does not summarize the central tendency of the data well by itself.

Interval data are similar to ratio data in that it is possible to carry out detailed mathematical operations

on them. As a result, it is possible to take the mean and the median as measures of central tendency. However, interval data lack a true 0 value.

For example, in measuring household size, it is conceivable that a household can possess very large numbers of members, but generally this is rare. Many households have fewer than 10 members; however, some modern extended families might run well into double digits. At the extreme, it is possible to observe medieval royal or aristocratic households with potentially hundreds of members. However, it is nonsensical to state that a household has zero members. It is also nonsensical to say that a specific household has 1.75 members. However, it is possible to say that the mean household size in a geographic region (a country, province, or city) is 2.75 or 2.2 or some other number. For interval data, the mode, the median, and the mean frequently provide valuable but different information about the central tendencies of the data. The mean may be heavily influenced by large low-prevalence values in the data; however, the median and the mode are much less influenced by them.

As an example of the role of the mode in summarizing interval data, if a researcher were interested in comparing the household size on different streets, A Street and B Street, he or she might visit both and record the following household sizes:

A Street : {3, 1, 6, 2, 1, 1, 2, 3, 2, 4, 2, 1, 4};

B Street : {2, 5, 3, 6, 7, 9, 3, 4, 1, 2, 1}.

Comparing the measures of central tendency (A Street: Mean = 2.5, Median = 2, Mode = 1 and 2; B Street: Mean = 3.8, Median = 3, Mode = 3) gives a clearer picture of the nature of the streets than any one measure of central tendency in isolation.

For data in *ordinal scales*, not only is there no absolute zero, but one can also rank the elements only in order of value. For example, a person could be asked to rank items on a scale of 1 to 5 in terms of his or her favorite. Likert-type scales are an example of this sort of data. A value of 5 is greater than a value of 4, but an increment from 4 to 5 does not necessarily represent the same increase in preference that an increase from 1 to 2 does. Because of these characteristics, reporting the median and the mode for this type of data makes sense, but the mean does not.

In the case of nominal-scale data, the mode is the only meaningful measure of central tendency. Nominal data tell the analyst nothing about the order of the data. In fact, data values do not even need to be labeled as numbers. One might be interested in which number a randomly selected group of hockey players at a hockey camp wear on their jersey back home in their

regular hockey league. One could select from two groups:

Group 1: {1, 3, 4, 4, 4, 7, 7, 10, 11, 99};

Group 2: {1, 4, 8, 9, 11, 44, 99, 99, 99, 99}.

For these groups, taking the mean and the median are meaningless as measures of central tendency (the number 11 does not represent more value than 4). However, the mode of Group 1 is 4, and the mode of Group 2 is 99. With some background information about hockey, the analyst could hypothesize which populations the two groups are drawn from. Group 2 appears to be made up of a younger group of players whose childhood hero is Wayne Gretzky (number 99), and Group 1 is likely made up of an older group of fans of Bobby Orr (number 4).

Another interesting property of the mode is that the data do not actually need to be organized as numbers, nor do they need to be translated into numbers. For example, an analyst might be interested in the first names of CEOs of large corporations in the 1950s. Examining a particular newspaper article, the analyst might find the following names:

Names: {Ted, Gerald, John, Martin, John,
Peter, Phil, Peter, Simon, Albert, John}

In this example, the mode would be *John*, with three listings. As this example shows, the mode is particularly useful for textual analysis. Unlike the median and the mean, it is possible to take counts of the occurrence of words in documents, speech, or database files and to carry out an analysis from such a starting point.

Examination of the variation of nominal data is also possible by examining the frequencies of occurrences of entries. In the above example, it is possible to summarize the results by stating that John represents 3/11 (27.3%) of the entries, Peter represents 2/11 (18.2%) of the entries, and that each other name represents 1/11 (9.1%) of the entries. Through a comparison of frequencies of occurrence, a better picture of the distribution of the entries emerges even if one does not have access to other measures of central tendency.

A Tool for Measuring the Skew of a Distribution

Skew in a distribution is a complex topic; however, comparing the mode to the median and the mean can be useful as a simple method of determining whether data in a distribution are skewed. A simple example is as follows. In a workplace a company offers free college tuition for the children of its employees, and the administrator of the plan is interested in the amount of

tuition that the program may have to pay. For simplicity, take three different levels of tuition. Private university tuition is set at \$30,000, out-of-state-student public university tuition is set at \$15,000 and in-state tuition is set at \$5,000.

In this example, 10 students qualify for tuition coverage for the current year. The distribution of tuition amounts for each student is as follows:

{5,000, 5,000, 5,000, 5,000, 5,000, 15,000,
15,000, 15,000, 30,000, 30,000}

Hence, the mode is \$5,000. The median is equal to $(15,000 + 5,000)/2 = \$10,000$. The mean = \$13,000. The tuition costs are skewed toward low tuition, and therefore the distribution has a negative skew.

A positively skewed distribution would occur if the tuition payments were as follows:

{30,000, 30,000, 30,000, 30,000, 30,000,
15,000, 15,000, 15,000, 5,000, 5,000}

Now the mode is \$30,000, the median is $(30,000 + 15,000)/2 = \$22,500$, and the mean = \$20,500.

Finally, the following observations are possible:

{30,000, 30,000, 30,000, 15,000, 15,000,
15,000, 15,000, 15,000, 5,000, 5,000}

In this case, the mode is \$15,000, the median is \$15,000, and the mean is \$17,500. The distribution has much less skew and is nearly symmetric.

The concept of skew can be dealt with using very complex methods in mathematical statistics; however, often simply reporting the mode together with the median and the mean is a useful method of forming first impressions about the nature of a distribution.

MODEL FIT

How well does a theoretical model fit a data set? For confirmatory factor analysis and structural equation modeling, this question is answered using fit indices, a process known as *goodness-of-fit*. The estimation of fit indices is based on testing the null hypothesis of $\Sigma = \Sigma(\theta)$. A test statistic allows the testing of the null hypothesis that the model specified by the researcher [Σ] leads to a reproduction of the population covariance matrix of the observed variables [$\Sigma(\theta)$] and a comparison of the fit of other various models. To assess this goodness-of-fit, various fit indices—absolute and relative fit indices—have been developed (see Table 1).

Estimating the Model

The most common methods for estimation are based on the statistical theory that forms the basis of normal, elliptical, and arbitrary distribution estimators; they are maximum likelihood, generalized least squares, and asymptotic distribution-free approaches, respectively. These estimation procedures are iterative—the

calculations performed are iterated until the best parameter estimation is obtained.

Absolute Fit Indices

Absolute fit indices are measures based on a theoretical model compared to the fit of a baseline model. Baseline models are either an independence model, whereby it is assumed that the observed variables are measured without error, or a null model, whereby all parameters are fixed to zero. Typically, values of these measures range from zero (no fit) to 1 (perfect fit). Common fit indices include model *chi-square* (χ^2), root mean square error of approximation (RMSEA), standardized root mean square residual (SRMR), goodness-of-fit index, adjusted goodness-of-fit (AGFI), Bentler–Bonett Normed Fit Index, and comparative fit index (CFI).

Relative Fit Indices

Relative fit indices are comparisons between models or descriptive measures of model parsimony, used primarily when competing models are being compared. Common fit indices include delta *chi-square* ($\Delta\chi^2$), Akaike

Table 1 Fit Indices for Structural Equation Modeling

Fit Index	Description	Value for Good Fit
Absolute fit indices		
Model <i>chi-square</i> (χ^2)	χ^2 assesses overall fit and the discrepancy between the sample and model covariance matrices or H_0 : The model fits perfectly. It is sensitive to sample size.	p value < .05
Goodness-of-fit (GFI) and adjusted goodness-of-fit (AGFI)	GFI is the proportion of variance accounted for by the estimated population covariance. AGFI is the proportion of the variance in the covariance matrix accounted for but adjusted for number of parameters.	GFI $\geq$ 0.95, AGFI $\geq$ 0.90
Bentler–Bonett Normed Fit Index (NFI)	The NFI provides the proportion of variance improvement over the null hypothesis of the model of interest. For example, NFI = 0.96 improves the fit by 96% over the null model.	NFI $\geq$ 0.95
Comparative Fit Index (CFI)	CFI is a revised form of NFI, which is not sensitive to sample size. It provides the fit of a null model.	CFI $\geq$ 0.90
Root mean square error of approximation (RMSEA)	RMSEA is a measure of the discrepancy between the sample covariance matrix and the model covariance matrix, taking into account the number of parameters. It is a parsimony-adjusted index.	RMSEA < 0.08
Standardized root mean square residual (SRMR)	SRMR is the square-root of the difference between the residuals of the sample covariance matrix and the hypothesized model. When measured variables vary in range, SRMR is a better choice.	SRMR < 0.08

(Continued)

Table I Continued

<i>Fit Index</i>	<i>Description</i>	<i>Value for Good Fit</i>
Relative fit indices		
Delta <i>chi-square</i> ($\Delta\chi^2$)	$\Delta\chi^2$ is the difference between the χ^2 values of two models estimated with the same data. It can be used to compare several models for best fit. The smallest χ^2 represents the best model fit.	$\Delta\chi^2, p$ value < .05
Akaike information criterion (AIC)	AIC is a comparative measure of fit when different models are estimated. Lower values indicate a better fit and so the model with the lowest AIC is the best fitting model. Each model can be ranked from best to worst based on the fit.	$\Delta\text{AIC}, p$ value < .05
Bollen's Incremental Fit Index (IFI)	The IFI adjusts NFI for sample size and degrees of freedom but the IFI can sometimes exceed 1.	$\text{IFI} \geq 0.90$
Tucker–Lewis Index (TLI) and Bentler–Bonett Nonnormed Fit Index (NNFI)	The TLI—same as the NNFI—avoids problems of negative values (sometimes fall beyond the 0 to 1 range). TLI is preferred for small samples (e.g., <200).	$\text{TLI} \geq 0.95, \text{NNFI} \geq 0.95$
Bayesian information criterion (BIC)	The probability of selecting a BIC of a true model increases with the size of the data set in Bayesian probability. It is a comparative measure of fit between different models. The more complex models will have a worse index; lower values indicate a better fit.	$\Delta\text{BIC}, p$ value < .05

information criterion (AIC), Bollen's Incremental Fit Index, Tucker–Lewis Index (TLI), Bentler–Bonett Non-normed Fit Index, and Bayesian information criterion (BIC).

Interpreting Fit

Most software packages (e.g., EQS, AMOS, LISREL) provide several indices that represent the different classes of fit criteria. Usually the *chi-square* value, AGFI, SRMR, and RMSEA are presented as indicators of goodness of fit.

For model comparisons, the *chi-square* difference test ($\Delta\chi^2$) and AIC are examined. It is recommended that multiple fit indices such as the CFI in combination with SRMR and RMSEA should be reported, as this combination tends not to reject models under nonrobust conditions (e.g., violations of multinormality). Generally models with $\text{AGFI} \geq 0.90$; $\text{CFIs} \geq 0.95$, $\text{SRMR} < 0.01$, and $\text{RMSEA} < 0.08$ are considered a good fit (see Table 1).

Finally, model selection should be guided by the principles of parsimony: The simplest model that fits the data is selected. If the fit is acceptable, the proposed relationships in the measurement model between the latent and the observed variables and in the structural models between the latent variables are supported by

the data. If the fit is considered poor (e.g., $\text{CFI} < 0.80$), the model can be respecified. Several factors can affect fit indices, including number of variables in the model, number of parameters to be estimated, model complexity, and the reliability and validity of the measured variables.

Reporting Model Fit

At least three indices should be reported for model fit: (1) χ^2 with *df* and *p* value, (2) CFI, and (3) RMSEA or SRMR. In assessing competing models, at least $\Delta\chi^2$ and TLI should be reported. Additional indices can be reported to provide a thorough understanding of the fit of a null model (e.g., AGFI) or competing models (e.g., AIC or BIC).

MODELS

It used to be said that models were dispensable aids to formulating and understanding scientific theories, perhaps even props for poor thinkers. This negative view of the cognitive value of models in science contrasts with today's view that they are an essential part of the development of theories, and more besides. Contemporary studies of scientific practice make it clear that models play genuine and indispensable cognitive roles in science, providing a basis for scientific reasoning. This entry describes types and functions of models commonly used in scientific research.

Types of Models

Given that just about anything can be a model of something for someone, there is an enormous diversity of models in science. The many senses of the word *model* that stem from this bewildering variety Max Wartofsky has referred to as the “model muddle.” It is not surprising, then, that the wide diversity of models in science has not been captured by some unitary account. However, philosophers such as Max Black, Peter Achinstein, and Rom Harré have provided useful typologies that impose some order on the variety of available models. Here, discussion is confined to four different types of model that are used in science: scale models, analogue models, mathematical models, and theoretical models.

Scale Models

As their name suggests, scale models involve a change of scale. They are always models of something, and they typically reduce selected properties of the objects they represent. Thus, a model airplane stands as a miniaturized representation of a real airplane. However, scale models can stand as a magnified representation of an object, such as a small insect. Although scale models are constructed to provide a good resemblance to the object or property being modeled, they represent only selected relevant features of the object. Thus, a model airplane will almost always represent the

fuselage and wings of the real airplane being modeled, but it will seldom represent the interior of the aircraft. Scale models are a class of iconic models because they literally depict the features of interest in the original. However, not all iconic models are scale models, as for example James Watson and Francis Crick's physical model of the helical structure of the DNA molecule. Scale models are usually built in order to present the properties of interest in the original object in an accessible and manipulable form. A scale model of an aircraft prototype, for example, may be built to test its basic aerodynamic features in a wind tunnel.

Analogue Models

Analogue, or analogical, models express relevant relations of analogy between the model and the reality being represented. Analogue models are important in the development of scientific theories. The requirement for analogical modeling often stems from the need to learn about the nature of hidden entities postulated by a theory. Analogue models also serve to assess the plausibility of our new understanding of those entities.

Analogical models employ the pragmatic strategy of conceiving of unknown causal mechanisms in terms of what is already familiar and well understood. Well-known examples of models that have resulted from this strategy are the molecular model of gases, based on an analogy with billiard balls in a container; the model of natural selection, based on an analogy with artificial selection; and, the computational model of the mind, based on an analogy with the computer.

To understand the nature of analogical modeling, it is helpful to distinguish between a model, the source of the model, and the subject of the model. From the known nature and behavior of the source, one builds an analogue model of the unknown subject or causal mechanism. To take the biological example just noted, Charles Darwin fashioned his model of the subject of natural selection by reasoning analogically from the source of the known nature and behavior of the process of artificial selection. In this way, analogue models play an important creative role in theory development. However, this role requires the source from which the model is drawn to be different from the subject that is modeled. For example, the modern computer is a well-known source for the modeling of human cognition, although our cognitive apparatus is not generally thought to be a real computer. Models in which the source and the subject are different are sometimes called *paramorphs*. Models in which the source and the subject are the same are sometimes called *homeomorphs*. The paramorph can be an iconic, or pictorial, representation of real or imagined things. It is iconic

paramorphs that feature centrally in the creative process of theory development through analogical modeling.

In evaluating the aptness of an analogical model, the analogy between its source and subject must be assessed, and for this one needs to consider the structure of analogies. The structure of analogies in models comprises a positive analogy in which source and subject are alike, a negative analogy in which source and subject are unlike, and a neutral analogy where we have no reliable knowledge about matched attributes in the source and subject of the model. The negative analogy is irrelevant for purposes of analogical modeling. Because we are essentially ignorant of the nature of the hypothetical mechanism of the subject apart from our knowledge of the source of the model, we are unable to specify any negative analogy between the model and the mechanism being modeled. Thus, in considering the plausibility of an analogue model, one considers the balance of the positive and neutral analogies. This is where the relevance of the source for the model is spelled out.

An example of an analogue model is Rom Harré's rule-model of microsocial interaction, in which Erving Goffman's dramaturgical perspective provides the source model for understanding the underlying causal mechanisms involved in the production of ceremonial, argumentative, and other forms of social interaction.

Mathematical Models

In science, particularly in the social and behavioral sciences, models are sometimes expressed in terms of mathematical equations. Mathematical models offer an abstract symbolic representation of the domain of interest. These models are often regarded as formalized theories in which the system modeled is projected on the abstract domain of sets and functions, which can be manipulated in terms of numerical reasoning, typically with the help of a computer. For example, factor analysis is a mathematical model of the relations between manifest and latent variables, in which each manifest variable is regarded as a linear function of a common set of latent variables and a latent variable that is unique to the manifest variable.

Theoretical Models

Finally, the important class of models known as theoretical models abounds in science. Unlike scale models, theoretical models are constructed and described through use of the scientist's imagination; they are not constructed as physical objects. Further, unlike scale, analogical, and mathematical models, the

properties of theoretical models are better known than the subject matter that is being modeled.

A theoretical model of an object, real or imagined, comprises a set of assumptions about that object. The Watson-Crick model of the DNA molecule and Markov models of human and animal learning are two examples of the innumerable theoretical models to be found in science. Theoretical models typically describe an object by ascribing to it an inner mechanism or structure. This mechanism or structure is frequently invoked in order to explain the behavior of the object. Theoretical models are acknowledged for their simplifying approximation to the object being modeled, and they can often be combined with other theoretical models to help provide a comprehensive understanding of the object.

Data, Models, and Theories

Data Models

In the 1960s, Patrick Suppes drew attention to the fact that science employs a hierarchy of models. He pointed out that theoretical models, which are high in the hierarchy, are not compared directly with empirical data, but with models of the data, which are lower in the hierarchy.

Data on their own are intractable. They are often rich, complex, and messy and, because of these characteristics, cannot be explained. Their intractability is overcome by reducing them into simpler and more manageable forms. In this way, data are reworked into models of data. Statistical methods play a prominent role in this regard, facilitating operations to do with assessing the quality of the data, the patterns they contain, and the generalizations to which they give rise. Because of their tractability, models of the data can be explained and used as evidence for or against theoretical models. For this reason, they are of considerable importance in science.

Models and Theories

The relationship between models and theories is difficult to draw, particularly given that they can both be conceptualized in different ways. Some have suggested that theories are intended as true descriptions of the real world, whereas models need not be about the world, and therefore need not be true. Others have drawn the distinction by claiming that theories are more abstract and general than models. For example, evolutionary psychological theory can be taken as a prototype for the more specific models it engenders, such as those of differential parental investment and

the evolution of brain size. Relatedly, Ronald Giere has argued that a scientific theory is best understood as comprising a family of models and a set of theoretical hypotheses that identify things in the world that apply to a model in the family.

Yet another characterization of models takes them to be largely independent of theories. In arguing that models are “autonomous agents” that mediate between theories and phenomena, Margaret Morrison contends that they are not fully derived from theory or data. Instead, they are technologies that allow one to connect abstract theories with empirical phenomena. Some have suggested that the idea of models as mediators does not apply to the behavioral and biological sciences because there is no appreciable gap between fundamental theory and phenomena in which models can mediate.

The Functions of Models

Representation

Models can variously be used for the purposes of systematization, explanation, prediction, control, calculation, derivation, and so on. In good part, models serve these purposes because they can often be taken as devices that represent parts of the world. In science, representation is arguably the main function of models. However, unlike scientific theories, models are generally not thought to be the sort of things that can be true or false. Instead, we may think of models as having a kind of similarity relationship with the object that is being modeled. With analogical models, for example, the similarity relationship is one of analogy. It can be argued that in science, models and theories are different representational devices. Consistent with this distinction between models and theories, William Wimsatt has argued that science often adopts a deliberate strategy of adopting false models as a means by which we can obtain truer theories. This is done by localizing errors in models in order eliminate other errors in theories.

Abstraction and Idealization

It is often said that models provide a simplified depiction of the complex domains they often represent. The simplification is usually achieved through two processes: abstraction and idealization. Abstraction involves the deliberate elimination of those properties of the target that are not considered essential to the understanding of that target. This can be achieved in various ways; for example, one can ignore the properties, even though they continue to exist; one can

eliminate them in controlled experiments; or one can set the values of unwanted variables to zero in simulations. By contrast, idealization involves transforming a property in a system into one that is related, but which possesses desirable features introduced by the modeler. Taking a spheroid object to be spherical, representing a curvilinear relation in linear form, and assuming that an agent is perfectly rational are all examples of idealization. Although the terms *abstraction* and *idealization* are sometime used interchangeably, they clearly refer to different processes. Each can take place without the other, and idealization can in fact take place without simplification.

Monte Carlo Simulation

A Monte Carlo simulation is a methodological technique used to evaluate the empirical properties of some quantitative method by generating random data from a population with known properties, fitting a particular model to the generated data, collecting relevant

information of interest, and replicating the entire procedure a large number of times (e.g., 10,000) in order to obtain properties of the fitted model under the specified condition(s). Monte Carlo simulations are generally used when analytic properties of the model under the specified conditions are not known or are unattainable. Such is often the case when no closed-form solutions exist, either theoretically or given the current state of knowledge, for the particular method under the set of conditions of interest. When analytic properties are known for a particular set of conditions, Monte Carlo simulation is unnecessary. Due to the computational tediousness of Monte Carlo methods because of the large number of calculations necessary, in practice they are essentially always implemented with one or more computers.

A Monte Carlo simulation study is a systematic investigation of the properties of some quantitative method under a variety of conditions in which a set of Monte Carlo simulations is performed. Thus, a Monte Carlo simulation study consists of the findings from applying a Monte Carlo simulation to a variety of conditions. The goal of a Monte Carlo simulation study is often to make general statements about the various properties of the quantitative method under a wide range of situations. So as to discern the properties of the quantitative method generally, and to search for inter-action effects in particular, a fully crossed factorial design is often used, and a Monte Carlo simulation is performed for each combination of the situations in the factorial design. After the data have been collected from the Monte Carlo simulation study, analysis of the data is necessary so that the properties of the quantitative procedure can be discerned. Because such a large number of replications (e.g., 10,000) are performed for each condition, the summary findings from the Monte Carlo simulations are often regarded as essentially population values, although confidence intervals for the estimates is desirable.

The general rationale of Monte Carlo simulations is to assess various properties of estimators and/or procedures that are not otherwise mathematically tractable. A special case of this is comparing the nominal and empirical values (e.g., Type I error rate, statistical power, standard error) of a quantitative method. Nominal values are those that are specified by the analyst (i.e., they represent the desired), whereas empirical values are those observed (i.e., they represent the actual) from the Monte Carlo simulation study. Ideally, the nominal and empirical values are equivalent, but this is not always the case. Verification that the nominal and empirical values are consistent can be the primary motivation for using a Monte Carlo simulation study.

As an example, under certain assumptions the standardized mean difference follows a known distribution, which in this case allows for exact analytic confidence intervals to be constructed for the population standardized mean difference. One of the assumptions on which the analytic procedure is based is that in the population, the scores within each of the two groups distribute normally. In order to evaluate the effectiveness of the (analytic) approach to confidence interval formation when the normality assumption is not satisfied, Ken Kelley implemented a Monte Carlo simulation study and compared the nominal and empirical confidence interval coverage rates. Kelley also compared the analytic approach to confidence interval formation using two bootstrap approaches so as to determine whether the bootstrap performed better than the analytic approach under certain types of nonnormal data. Such comparisons require Monte Carlo simulation studies because no formula-based comparisons are available as the analytic procedure is based on the normality assumption, which was (purposely) not realized in the Monte Carlo simulation study.

As another example, under certain assumptions and an asymptotically large sample size, the sample root mean square error of approximation (RMSEA) follows a known distribution, which allows confidence intervals to be constructed for the population RMSEA. However, the effectiveness of the confidence interval procedure had not been well known for finite, and in particular small, sample sizes. Patrick Curran and colleagues have evaluated the effectiveness of the (analytic) confidence interval procedure for the population RMSEA by specifying a model with a known population RMSEA, generating data, forming a confidence interval for the population RMSEA, and replicating the procedure a large number of times. Of interest was the bias when estimating the population RMSEA from sample data and the proportion of confidence intervals that correctly bracketed the known population RMSEA, so as to determine whether the empirical confidence interval coverage was equal to the nominal confidence interval coverage (e.g., 90%).

A Monte Carlo simulation is a special case of a more general method termed the *Monte Carlo method*. The Monte Carlo method, in general, uses many sets of randomly generated data under some input specifications and applies a particular procedure or model to each set of the randomly generated data so that the output of interest from each fit of the procedure or model to the randomly generated data can be obtained and evaluated. Because of the large number of results of interest from the fitted procedure or model to the randomly generated data sets, the summary of the results describes the

properties of how the procedure or model works in the specified input conditions.

A particular implementation of the Monte Carlo method is a method known as *Markov Chain Monte Carlo*, which is a method used to sample from various probability distributions based on a specified model in order to form sample means for approximating expectations. Markov Chain Monte Carlo techniques are most often used in the Bayesian approach to statistical inference, but they can also be used in the frequentist approach.

The term *Monte Carlo* was coined in the mid-1940s by Nicholas Metropolis while working at the Los Alamos National Laboratory with Stanislaw Ulam and John von Neumann, who proposed the general idea and formalized how determinate mathematical problems could be solved with random sampling from a specified model a large number of times, because of the games of chance commonly played in Monte Carlo, Monaco, with the idea of repeating a process a larger number of times and then examining the outcomes. The Monte Carlo method essentially replaced what was previously termed *statistical sampling*. Statistical sampling was used famously by William Sealy Gossett, who published under the name *Student*, before finalizing the statistical theory of the *t* distribution and was reported in his paper to show a comparison of empirical and nominal properties of the *t* distribution.

MORTALITY

Confidence in research findings and their interpretation is essential to good science. It is through attention to the internal validity of the study design that confidence can be assured in experimental studies, which attempt to show causation. These studies are common in testing theoretical predictions and in evaluating the efficacy of interventions, whether in health care, in the classroom, in organizations, or in other settings. In designing studies with strong internal validity, care is taken to ensure that the hypothesis of causation, “X causes Y,” can be clearly posited. Numerous factors can blur the interpretation of findings, referred to as *threats to internal validity*. One of these is mortality or the loss of subjects in a study. This entry provides an overview of the problems posed by such loss, how to recognize the problem, how to manage it in analysis, and how to minimize the occurrence of mortality.

The Problem of Dropouts From Research Studies

Dropout rates in experimental studies, particularly in intervention designs and clinical trials, average as high as 20–30% but may reach 80% or even more. Subjects may drop out for multiple reasons including but not limited to the time commitment and inconvenience of participation, untoward effects attributed to the study manipulation or intervention, perception of risk particularly if the subjects believe themselves to be in the control condition, relocation, and significant life change. Even the method of collecting data can influence participation rates. The loss of subjects affects the statistical power of the study to detect true differences between groups as well as introduces the risk of bias in interpreting findings. Indeed, some studies may not be able to be successfully completed due to high mortality rates.

Mortality and Study Power

As part of the design of an experimental study, the *power* to detect a causal relationship between X and Y is a function of both the true size of the effect and the size of the sample selected for the study. If the effect of X on Y is small, then it will take a large sample to

detect it. If the effect of X on Y is large, then a large sample is not needed. To optimize the probability of finding that effect without wasting either money or effort, a sample size calculation is undertaken with the targeted power and statistical significance preset and the probable effect size determined from a review of previous studies or a pilot study.

Should subjects drop out of a study, the number needed to confidently detect the effect of X on Y is challenged. It may not be possible to find the effect even if it is there. This is referred to as a *Type II error*, which is a failure to reject the null hypothesis when it is actually false. This type of error, unfortunately, is not uncommon in smaller research studies and may lead to promising interventions being rejected early in the investigative process.

Efforts are commonly undertaken to reduce the loss of power due to the loss of sample size due to attrition. First, all studies of an experimental nature require a power estimate to determine the number of subjects needed to detect an effect of X on Y . This is followed by an assessment in the literature of the typical dropout rate among this study population in previous studies. Pilot studies may also be undertaken to determine the ability to retain subjects in the study. Commonly, the investigator then over-recruits the calculated sample size by the percentage of dropouts seen in pilot work and/or previous research by the needed sample size divided by 1 minus that percentage expected to drop out. Optimistically, the investigator hopes the attrition rate is no higher than planned and power is retained. Efforts may also be directed toward subject retention during the course of the study.

Mortality and Differential Attrition Bias

A second significant problem when attrition occurs in experimental or intervention research is that of bias in interpreting results of studies. A key factor is whether the subject's data are missing at random or not. Bias occurs when the dropouts are not equivalent across groups in characteristics of the subjects and/or in the study time line. That is, there may be more dropouts in a particular arm of the study than in the other arm. Subject characteristics may vary. For example, younger adults may be more likely to drop out than older adults. Subjects in one group may be likely to drop out earlier in the study. The later recruited cohort may be more likely to drop out than the earlier cohort. In multicenter studies, subjects may be more likely to drop out from one center than from others. Control subjects may drop out of the control arm and obtain intervention (drop in). Bias in interpreting outcomes, safety, and identification of untoward effects or predictor variables

may result from this differential attrition as well as errors in generalization of results.

The impact of differential attrition is most important when it is nonrandom and affects the outcomes of the study itself. A hypothetical example is used here to illustrate the impact of various types of biases associated with dropout in experimental research. Assume the study is designed to test the impact of an intervention on chronic pain management. The study has three arms: a control condition that receives usual clinical care, an intervention arm that offers a low-dose drug, and an intervention arm that offers a high-dose drug. More subjects drop out of the high-dose arm than either of the other two arms due to side effects from the drug. If the trial reports on the subjects who provide a final assessment, there is risk that the high- and low-dose conditions will be reported as having equal and low side effects when considerations of the dropouts would indicate the high-dose drug had greater side effects and lower tolerances. Similarly, if the control subjects dropped out of the no-treatment condition and convinced their providers to prescribe the treatment that the intervention was using, the study might report there is no difference between the drug and usual care. If older adults were more likely to drop out of the study, the study might report that the drug is effective across the life span when actually the older adults found the drug less tolerable and did not stay on it.

This risk of misinterpretation of study outcomes due to differential attrition bias is present in any study with dropouts. Several processes are important in avoiding the risk of misinterpretation of study outcomes. The first is to identify the reason for dropping out for each subject. Then the proportion of dropouts in each category of reasons can be calculated and inform the interpretation of findings. For example, if 70% of dropouts occurred because of a specific side effect of treatment, this helps to inform findings on treatment side effects.

The second process is a thorough analysis of the dropouts and reporting these data as a component of the study report. In the aforementioned hypothetical case, the investigator would report the average age and range of the dropouts *versus* the retained subjects, the average duration in the trial, the distribution across treatment conditions of the dropouts and retained subjects, as well as other factors such as differences in symptom reports between groups at the point of the average dropout, gender distribution, and any additional measures used in the evaluation of treatment efficacy and safety.

A third process is to ensure as much data as possible at the end of the study. This entails an effort to enlist dropouts to return for a final data assessment. While the power to detect differences may be weakened from

the lack of adherence to intervention protocols during the dropout period, this analysis reduces the bias from selective attrition.

A fourth process is to conduct an intention-to-treat analysis. This is a recommended analysis for experimental studies testing interventions. In an intention-to-treat analysis, every person who was randomized into the study is included in the outcome assessment. As previously noted, efforts are made to obtain final outcome data from the subjects who have dropped out. For subjects who do not provide data at the end of the study, various methods can be used to impute or estimate data for the final outcome assessment. One method is to replace the data for the dropout with the mean or average data for the sample in that group. For example, if a person in a weight loss study dropped out, the average weight loss (or gain) in the arm is assigned. A second method is to carry forward to the outcome data the last value recorded for the dropout. If that same weight loss subject dropped out of a 6-month study at 3 months, then their weight at 3 months would be used for the 6-month end of study. Other more sophisticated methods of imputation are available depending upon the nature of the data, the design of the study, and the number of data points to be imputed.

Strategies to Reduce Dropouts in Experimental Designs

Due to the problems created by dropouts in experimental designs. The best strategy is to prevent the problem to the extent possible. This requires an understanding of why persons might drop out. In some cases, it is not the result of the subject's decision; rather, the investigator may decide to terminate participation. For example, an individual may be withdrawn because they are no longer capable of completing the intervention/manipulation activities. An individual might be participating in an exercise study but breaks their leg and is no longer able to exercise. The investigator may choose to withdraw the subject at that point.

Other reasons may be more attributable to the subject choosing to withdraw. One reason is that participation becomes a burden due to the number of visits or surveys or having to take time off work or school to participate. The perceived benefit of participating does not compensate for the inconvenience or burden of participation. Another reason may be that the subject's expectations about study participation do not match with the reality of participating. It is not uncommon for study subjects to fail to understand the commitment and purpose or to expect benefits beyond that laid out in the consent form. Many research subjects join

research with altruistic objectives. If those perceptions are not sustained, the subject may lose interest. Further, participation may actually reduce the subject's quality of life through negative physical or psychological impact.

Design to Retain Subjects

Numerous strategies can be undertaken to design studies to promote subject retention. One of importance is to provide a consent process that fully informs the potential subject of what is expected. Consideration needs to be given to the reading levels and health literacy levels of the population being studied, the potential of multimedia presentations of the study, and the possibility of some simulated activity of the study demands. A multicenter clinical trial some years ago required the prospective subjects to carry out for 1 month behaviors similar to those required by the study. Fifteen years later, the majority of the subjects were still participating in the longitudinal follow-up. These types of activities fully inform and provide realistic expectations for participation.

Activities can also be taken within the conduct of the trial itself. Convenient scheduling, appointment reminders, limited waiting times, reimbursement of participant costs like parking or bus fares, repeated acknowledgment of the subjects' contributions, and informing subjects of findings as they are ready for dissemination are some of the activities that can be utilized and have been found to be valuable. Ongoing communication and rapid follow-up of missed appointments are also strategies that have proven successful. Follow-up communication with subjects has shown that they like to feel they are helping others, are among the *first to know*, and aren't being inconvenienced. When dropouts do occur, it is important to have plans in place to pursue them and to make every effort to recruit them back into the study, even if that can only be for the final assessment. Projects within clinical trials have shown that *dropout retrieval* can be successful.

MPLUS

Mplus is a statistical modeling program with a focus on the estimation of latent variables developed by Linda Muthén and Bengt Muthén. It is a highly flexible program capable of estimating a wide variety of models and offering a range of estimators, options, and special features. Thus, Mplus can be useful for researchers with diverse needs related to their particular data and analytic framework. Mplus utilizes latent variables—unobserved variables inferred from observed data—to model hypothesized associations among concepts. The particular utility of Mplus is that the program models both continuous and categorical latent variables. Continuous latent variables are used in structural equation modeling (SEM) and similar techniques (e.g., path analysis, confirmatory factor analysis), as well as growth modeling, survival analysis, and time-series analysis. Categorical latent variables are utilized to estimate mixture models and similar techniques (e.g., latent class analysis, latent class growth analysis).

Because of its focus on latent variables, Mplus has been used fairly extensively by researchers employing SEM. Mplus has a number of utilities that make it useful to these researchers, including a variety of options for handling missing data, multiple estimators and algorithms, the ability to conduct Monte Carlo simulation studies, graphical tools, and a language generator. The Mplus website and user guide provide a large pool of sample studies and syntax. The publishers themselves are highly responsive to users, often providing fairly individualized responses in the Mplus discussion boards. However, there are also important limitations researchers should consider, including the closed-source nature (and therefore cost) of the program, the restricted compatibility with non-Windows operating systems, and data management weaknesses. This entry first describes the framework and capabilities of Mplus and then highlights its advantages and limitations.

Modeling Framework and Capabilities

Mplus utilizes a SEM framework that is highly flexible and therefore has a wide range of capabilities.

Framework

As previously noted, Mplus utilizes both continuous and categorical latent variables to estimate a wide variety of statistical models. Continuous latent factors can be estimated using continuous, categorical, censored, and count manifest variables. Associations among continuous latent factors, between continuous latent factors and manifest variables, and among manifest variables can be estimated using regression-based techniques (linear, tobit, probit or logit, multinomial, and poison or negative binomial regression for appropriate distributions). Continuous latent variables can thus be estimated in Mplus based on indicators with a number of different underlying distributions. Users can specify variable types and the program will use the appropriate regression-based technique. Mplus is, thus, highly useful for SEMs that include measurement and structural portions in the same model.

Mplus can also estimate categorical latent variables based on continuous, categorical, censored, and count manifest variables. That is, Mplus is capable of mixture modeling, in which unobserved classes are estimated based on observed data. Mixture analysis can capture unobserved heterogeneity in a given population. Subgroups may exist in any population with distinct distributions of and associations among variables of interest. Subgroups do not need to be known a priori but can be estimated based on data. Predictors and distal outcomes can be estimated to assess antecedents and consequences of group membership. Continuous and categorical variables can be combined to conduct mixture analysis with random effects and structural equation mixture modeling among other models.

Flexibility

Mplus is a highly flexible statistical program. The models previously described can all be modified to suit specific data and modeling needs. In particular, Mplus provides a number of options for handling missing data, including full information maximum likelihood (often the default setting) and Bayesian-based multiple imputation. Users can also specify listwise deletion. Mplus can handle complex survey data using predetermined population weights, can correct for clustering using a sandwich estimator, and can conduct multilevel analysis.

Mplus also supports a number of estimators and algorithms. Frequentist analysis can be conducted using maximum likelihood and weighted least squares estimators, and Bayesian estimation is available using Markov chain Monte Carlo algorithms. Robust standard errors and *chi-square* tests using a sandwich estimator, which are robust to non-normality and clustering in the data, are available for most models, and bootstrap standard errors, which are nonparametric tests, are also available for most models.

Given the wide variety of options available, Mplus provides users with a high degree of control over their models. To accomplish this, Mplus utilizes a fairly extensive syntax that may be unfamiliar to many users. Unlike many statistical programs in which a model can be specified on a single line of code on a larger syntax file (e.g., Stata, SPSS, R), individual syntax files specify a single model in Mplus. This structure is likely because of the amount of options available to users. Thus, coding a model in Mplus can be a complex process for novice users; however, Windows users have access to a (relatively limited) language generator. Coding in Mplus is also streamlined by the extensive use of pre-programmed default settings. By utilizing default settings, users can program relatively complex models with little syntax. Although these defaults are generally reasonable and in line with accepted standards and cut points, they may differ from a given researcher's needs and expectations. Users should familiarize themselves with defaults listed in the user guide.

Other Capabilities

Mplus has a number of other capabilities that may be of interest to researchers. The program can be used to conduct Monte Carlo simulation studies, which may be of particular interest for statisticians. There are also utilities for twin, sibling, and family genetics modeling. Windows users also have access to graphics based on their model, including histograms, scatterplots, and other graphical displays of results. User control of these graphics is quite limited, and users will likely require another program to produce publication-quality graphics.

Advantages

The principle advantage of Mplus is the high degree of flexibility previously outlined. Researchers with sufficient knowledge of the Mplus language can produce complex and highly specialized models particularized for their data and research question. As previously noted, learning the language to the degree necessary to

produce these models may be intimidating; however, there are numerous resources that are easily available. The official Mplus message boards are (as of this writing) highly active. Researchers having problems with their model can often find threads with advice from other researchers with similar issues. Also (as of this writing), the publishers are highly active on these message boards, offering individualized advice. The user guide is written in a fairly straightforward fashion and contains numerous generic examples of syntax. The Mplus website has a list of publications that make use of some of the more specialized Mplus features. Thus, there are substantial examples of syntax for newer users or for experienced users interested in making use of a novel feature.

Mplus has a robust user base, which is often important for researchers selecting a program. Because there is large body of users, there are resources in major publications, including research reports using special features of Mplus, and pedagogical articles with instructions on the use of Mplus. The Mplus program has been widely accepted in most fields that make use of SEM, mixture modeling, and higher order modeling. Thus, results from Mplus are typically considered valid by publications and other scholars (assuming no user error).

The Mplus algorithms are well optimized for most modern computers. Therefore, even fairly complex models converge relatively quickly in Mplus. This is often negligible in simple models (e.g., path models, SEM with few variables). However, given that one of the main advantages of Mplus is its ability to conduct complex and specialized analysis, small advantages in computing time can have large effects. Complex mixture and higher order models can take several minutes to several hours to converge due to computation complexity. Researchers may want to use bootstrapped confidence intervals that can require hundreds or even thousands of draws, further adding computing time. Thus, well-optimized software can have substantial effects on computing time for researchers using these complex models. Mplus also allows all users to make use of multicore processors, unlike other software that charges extra for that capability. Again, this can help reduce computing time for complex models.

Limitations

A primary limitation for researchers who are considering using Mplus is expense. Mplus is a closed-source program primarily aimed at academicians and is not available as a free distribution. Many of the innovative and interesting features of the program, including

mixture modeling and multilevel modeling, are only available as *add-ons* to the base program. Thus, users interested in making use of the aforementioned advantages must pay for the base package and for the add-ons. Discounts are available for those who purchase both add-ons and for universities and students.

Mplus does not have extensive tools for producing quality graphics and tables. As previously noted, the built-in plot tool is fairly restricted, and there is no option to easily export output into publication-ready tables. Unlike some other programs, Mplus does not have user-developed programs to perform these functions. Users will, therefore, often simply have to copy and paste from the output into Microsoft Excel or a similar program. Given the potential for user error in this process, typographical errors are more likely to appear in print when users transpose results by hand. Other programs that can automatically produce publication-quality graphics and tables (or can produce graphics and tables that can be easily made publication quality) are less likely to generate erroneous findings as a result of typographical errors.

Mplus is not used extensively in the private sector. This is likely because the flexibility and complex modeling capabilities of Mplus are not utilized much outside of academic research. For academic researchers, this is likely unimportant, but for students considering a career in the private sector, mastering a language like Python, SQL, or R, may be more valuable. Likely because of its limited adoption in the private sector and closed-source nature, Mplus has a limited presence on online forums like Stack Overflow and Quora. However, given the robust nature of the Mplus message boards, this may not be a major concern for many researchers.

Mplus has limited functionality on Apple and Linux devices. Specifically, the plot function is unavailable on devices using Apple OS. There is a utility to produce plots using R on Apple devices (however, at some point, users may simply choose to conduct the analysis in R altogether). Mplus is only available through command line prompts on Linux devices. Given the relatively limited adoption of Linux operating systems, this does not likely affect very many potential users. Linux users are also likely more used to command line prompts.

Finally, Mplus does not offer any meaningful data management utility. Users typically clean and prepare data for analysis in another program and then move the data to Mplus as a .csv file (though Mplus also supports other formats). The *DEFINE* command in Mplus does allow users to generate new variables based on those extant in the data set, but this command is relatively limited and cumbersome to use. Thus, the bulk of users will likely need to own and have

proficiency with another program that is designed for data management.

Broadly speaking, however, Mplus is a highly flexible and capable program that is useful for researchers with relatively simple and highly complex research models alike. There are numerous advantages that make Mplus an excellent choice for researchers, particularly researchers in academia who are interested in complex, longitudinal, multilevel, and/or higher order modeling. However, users considering Mplus should take into account its limitations, especially if cost and/or private-sector compatibility are major concerns.

MULTIDIMENSIONAL SCALING

Multidimensional scaling (MDS)—also called *principal coordinates analysis*—transforms a data table of distances (or dissimilarities) measured between a set of observations into a set of (Euclidean) coordinates for these observations that can, in turn, be used to plot the observations on a map, so that the (Euclidean) distances on the map between the observations best approximate their distances in the original distance matrix (see Figure 1 for a sketch of the method).

Definitions and Notations

MDS exists in two variations: *metric multidimensional scaling* (MMDS) to be used when the data are real distances (preferably Euclidean) and *nonmetric multidimensional scaling* (NMDS) when the data are simply dissimilarities. But first, some definitions are needed to describe the different varieties of MDS and their properties.

Figure 1 The Main Steps of Multidimensional Scaling: (1) Start With a Distance Matrix, (2) Transforms the Distance Matrix Into a Set of Factor Scores, and (3) Plot the Observations Using Their Factor Scores

Note: Here the distances on the map exactly recover the distances in the original matrix.

Distances

A distance noted d associates to a pair of objects from a given set (which could be denoted $\{a, b, \dots\}$) a number such that

- $d(a, b) \geq 0$ (positivity)
- $d(a, a) = 0$
- $d(a, b) = d(b, a)$ (symmetry)
- $d(a, b) \leq d(a, c) + d(c, b)$ (triangle inequality)

When only the first three axioms hold (i.e., the triangle inequality does not hold), d is called a *dissimilarity*. Note that, these axioms can easily be fulfilled. For example, if two objects are the same, their distance can be defined as $d(a, a) = 0$, if they are different, their distances can be set to $d(a, b) = 1$: Using only these two numbers satisfies all four axioms of a distance.

Of course, we are mostly familiar with Euclidean distances: In addition to the four axioms of a distance, Euclidean distances exist in spaces for which the Pythagorean theorem holds. In these spaces, the objects to be considered can be seen as points in a space whose position is specified by their coordinates. These objects—called *vectors*—are denoted by boldface lower case letters (e.g., $\mathbf{a}$). For example, in Figure 1, the position of vector $\mathbf{a}$ is specified by its coordinates of -8 on Dimension 1 and 0 on Dimension 2. Formally, this vector $\mathbf{a}$ is written as a column of numbers as

$$\mathbf{a} = \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} = \begin{bmatrix} -8 \\ 0 \end{bmatrix}. \quad (1)$$

When transposed, the vector $\mathbf{a}$ —now denoted $\mathbf{a}^T$ —becomes a row vector. For example

$$\mathbf{a}^T = \begin{bmatrix} a_1 \\ a_2 \end{bmatrix}^T = [a_1, a_2] = \begin{bmatrix} -8 \\ 0 \end{bmatrix}^T = [-8, 0]. \quad (2)$$

Euclidean Distance

The squared Euclidean distance between two vectors is computed from the Pythagorean theorem applied to

the coordinates of the vectors. For example, with $\mathbf{a}$ and $\mathbf{c}$ (see Figure 1) having coordinates

$$\mathbf{a} = \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} = \begin{bmatrix} -8 \\ 0 \end{bmatrix} \text{ and } \mathbf{c} = \begin{bmatrix} c_1 \\ c_2 \end{bmatrix} = \begin{bmatrix} 0 \\ -6 \end{bmatrix}, \quad (3)$$

the *squared* Euclidean distance $d(\mathbf{a}, \mathbf{c})$ is computed as

$$\begin{aligned} d^2(\mathbf{a}, \mathbf{c}) &= (a_1 - c_1)^2 + (a_2 - c_2)^2 \\ &= (8 - 0)^2 + (0 - 6)^2 = 64 + 36 = 100. \end{aligned} \quad (4)$$

The Euclidean distance is defined for vectors with any number of dimensions. Suppose that $\mathbf{a}$ and $\mathbf{b}$ are two vectors with I elements, the Euclidean distance between these two vectors is computed as

$$d^2(\mathbf{a}, \mathbf{b}) = (\mathbf{a} - \mathbf{b})^T (\mathbf{a} - \mathbf{b}). \quad (5)$$

Matrices

Matrices generalize vectors and are defined as tables of numbers. Matrices are often named from their number of rows and columns and are denoted with uppercase boldface letters. For example, the 4×2 coordinates matrix $\mathbf{F}$ from Figure 1 is written as

$$\mathbf{F}_{4 \times 2} = \mathbf{F} = \begin{bmatrix} f_{1,1} & f_{1,2} \\ f_{2,1} & f_{2,2} \\ f_{3,1} & f_{3,2} \\ f_{4,1} & f_{4,2} \end{bmatrix} = \begin{bmatrix} -8 & 0 \\ 8 & 0 \\ 0 & -6 \\ 0 & 6 \end{bmatrix}. \quad (6)$$

Metric Multidimensional Scaling

MMDS analyzes data tables that store the distances between a set of observations. MDS represents these observations as points on a map that are positioned to best approximate their distances in the original data table. To do so, MDS transforms the original distance matrix into coordinates—akin to the factor scores of principal component analysis (PCA)—which are then used to create these maps.

The basic idea of MMDS is to transform the original distance matrix into a cross-product matrix (i.e., a matrix akin to a covariance matrix) which is then decomposed with the eigen-decomposition method—a process equivalent to PCA. Just like PCA, MDS can be used with supplementary elements (also called *illustrative* or *out of sample* elements), which are elements that are not used in the original distance matrix but are projected onto the MMDS dimensions after these dimensions have been computed.

MMDS: Eigen-Analysis of a Distance Matrix

PCA is obtained by performing the eigen-decomposition of a matrix, which can be (1) a correlation matrix (i.e., the variables to be analyzed are centered and normalized), (2) a covariance matrix (i.e., the variables are centered but not normalized), or (3) a cross-product matrix (i.e., the variables are neither centered nor normalized). A distance matrix cannot be analyzed directly using the eigen-decomposition (because distance matrices are not positive semi-definite matrices which are the type of matrices that can be analyzed with PCA), but it can be transformed into an equivalent cross-product matrix, which can then be analyzed with an eigen-decomposition.

Theory of MMDS: Transforming a Distance Matrix Into a Cross-Product Matrix

In order to transform a distance matrix into a cross-product matrix, we start from the fact that the scalar product between two vectors can easily be transformed into a distance (recall that the scalar product between vectors corresponds to a cross-product matrix).

This distance can be rewritten in order to show the scalar product between vectors **a** and **b**:

$$d^2(\mathbf{a}, \mathbf{b}) = (\mathbf{a} - \mathbf{b})^T (\mathbf{a} - \mathbf{b}) = \mathbf{a}^T \mathbf{a} + \mathbf{b}^T \mathbf{b} - 2 \times (\mathbf{a}^T \mathbf{b}), \quad (7)$$

where $\mathbf{a}^T \mathbf{b}$ is the scalar product between **a** and **b**.

Suppose now that we have a set of I observations (i.e., vectors) each described by J variables; and that these data are stored into an I by J data matrix denoted **X**, the between observations cross-product matrix (denoted **S**) is then obtained as

$$\mathbf{S} = \mathbf{X}^T \mathbf{X}. \quad (8)$$

If we denote **s** the I by 1 vector of the diagonal elements of **S** and by **1** a vector of 1s, a between observation squared Euclidean distance matrix can be computed directly from the cross-product matrix as

$$\mathbf{D} = \mathbf{s} \mathbf{1}^T + \mathbf{1} \mathbf{s}^T - 2 \mathbf{S}. \quad (9)$$

(Note that the elements of **D** gives the *squared* Euclidean distance between rows of **S**.)

Equation 9 shows that a Euclidean distance matrix can be computed from a cross-product matrix. To perform MMDS, Equation 9 needs to be “reverted” in order to obtain a cross-product matrix from a distance matrix. But, there is one problem when implementing this idea, namely that *different* cross-product matrices can give the *same* distance. This can happen because distances are invariant by any change of origin. Therefore, in order to revert Equation 9, we need to impose an origin for the computation of the distance. An obvious choice is to choose the origin of the distance as the center of gravity of the dimensions. With this constraint, the cross-product matrix is obtained as follows.

First, define a mass vector denoted **m** whose I elements give the mass of the I rows of matrix **D**. These elements are all positive and their sum is equal to one:

$$\mathbf{m}_{1 \times I}^T \mathbf{1}_{I \times 1} = 1. \quad (10)$$

When all the rows have equal importance, each element is equal to $\frac{1}{I}$.

Second, define a $I \times I$ centering matrix denoted **Ξ** (read *big Xi*) equal to

$$\mathbf{\Xi} = \mathbf{I} - \mathbf{1} \mathbf{m}^T. \quad (11)$$

Finally, the cross-product matrix is obtained from matrix **D** as:

$$\mathbf{S} = -\frac{1}{2} \mathbf{\Xi} \mathbf{D} \mathbf{\Xi}^T. \quad (12)$$

The eigen-decomposition of this matrix gives

$$\mathbf{S} = \mathbf{U} \mathbf{\Lambda} \mathbf{U}^T \quad (13)$$

with

$$\mathbf{U}^T \mathbf{U} = \mathbf{I} \text{ and } \mathbf{\Lambda} \text{ diagonal matrix of eigenvalues.} \quad (14)$$

The factor scores (i.e., the projection of the rows on the principal components of the analysis of **S**) are obtained as

$$\mathbf{F} = \mathbf{U} \mathbf{\Lambda}^{\frac{1}{2}}. \quad (15)$$

These scores have the properties that their cross-product (i.e., their sum of squares) is equal to the eigenvalues:

$$\mathbf{F}^T \mathbf{F} = \mathbf{\Lambda}. \quad (16)$$

The map drawn from these factor scores gives now the best Euclidean approximation of the original distance matrix (or an exact Euclidean rendition, if the original data were a two-dimensional Euclidean distance).

Also the (Euclidean) distance matrix can directly be built back from these factor scores because

$$\mathbf{F}\mathbf{F}^T = \mathbf{S} \quad (17)$$

which in turn gives the original data matrix from Equation 9.

Note, incidentally, that some implementations of MMDS prefer to compute factor scores whose variance (rather than their sums of squares) equals their eigenvalues. In this case, the factor scores—denoted $\tilde{\mathbf{F}}$ —are computed as

$$\tilde{\mathbf{F}} = \mathbf{M}^{-\frac{1}{2}} \mathbf{U} \mathbf{\Lambda}^{\frac{1}{2}} \text{ (with } \mathbf{M} = \text{diag}\{\mathbf{m}\} \text{)}. \quad (18)$$

The *variance* of these scores now equals the eigenvalues:

$$\tilde{\mathbf{F}}^T \mathbf{M} \tilde{\mathbf{F}} = \mathbf{\Lambda}. \quad (19)$$

The distances read on the map are now *proportional* to the original distance.

A Toy Example

To illustrate the details of MMDS, we use the data from Figure 1. The distance data matrix is denoted $\mathbf{D}_{\text{Euclid}}$ and the matrix storing the Euclidean *squared* distance is denoted $\mathbf{D}$

$$\mathbf{D}_{\text{Euclid}} = \begin{bmatrix} 0 & 16 & 10 & 10 \\ 16 & 0 & 10 & 10 \\ 10 & 10 & 10 & 12 \\ 10 & 10 & 12 & 0 \end{bmatrix} \text{ and} \quad (20)$$

$$\mathbf{D} = \begin{bmatrix} 0 & 256 & 100 & 100 \\ 256 & 0 & 100 & 100 \\ 100 & 100 & 100 & 144 \\ 100 & 100 & 144 & 0 \end{bmatrix}.$$

The elements of the mass vector $\mathbf{m}$ are all equal to $\frac{1}{4}$;

$$\mathbf{m}^T = [.25 \ .25 \ .25 \ .25]. \quad (21)$$

The centering matrix is equal to

$$\mathbf{\Xi}_{4 \times 4} = \begin{bmatrix} .75 & -.25 & -.25 & -.25 \\ -.25 & .75 & -.25 & -.25 \\ -.15 & -.25 & .75 & -.25 \\ -.25 & -.25 & -.25 & .75 \end{bmatrix}.$$

The cross-product matrix is then equal to

$$\mathbf{S} = \begin{bmatrix} 64 & -64 & 0 & 0 \\ -64 & 64 & 0 & 0 \\ 0 & 0 & 36 & -36 \\ 0 & 0 & -36 & 36 \end{bmatrix}.$$

The eigen-decomposition of $\mathbf{S}$ gives

$$\mathbf{S} = \mathbf{U} \mathbf{\Lambda} \mathbf{U}^T \text{ with } \mathbf{U} = \begin{bmatrix} -\frac{1}{\sqrt{2}} & 0 \\ \frac{1}{\sqrt{2}} & 0 \\ 0 & -\frac{1}{\sqrt{2}} \\ 0 & \frac{1}{\sqrt{2}} \end{bmatrix} \text{ and} \quad (22)$$

$$\mathbf{\Lambda} = \begin{bmatrix} 128 & 0 \\ 0 & 72 \end{bmatrix}.$$

As in PCA, the eigenvalues are often transformed into percentage of explained variance (or inertia) in order to make their interpretation easier. Here, for example, we find that the first dimension “explains” 64% of the variance of the distances (i.e., $\frac{128}{128+72} = .64$).

We obtain the following matrix of scores (that can now be used to plot the Euclidean map of Figure 1)

$$\mathbf{F} = \mathbf{U} \mathbf{\Lambda}^{\frac{1}{2}} = \begin{bmatrix} -\sqrt{\frac{128}{2}} & 0 \\ \sqrt{\frac{128}{2}} & 0 \\ 0 & -\sqrt{\frac{72}{2}} \\ 0 & \sqrt{\frac{72}{2}} \end{bmatrix}$$

$$= \begin{bmatrix} -\sqrt{64} & 0 \\ \sqrt{64} & 0 \\ 0 & -\sqrt{36} \\ 0 & \sqrt{36} \end{bmatrix} = \begin{bmatrix} -8 & 0 \\ 8 & 0 \\ 0 & -6 \\ 0 & 6 \end{bmatrix}. \quad (23)$$

A More Realistic Example

This realistic example is derived from research reported in an article published by Jordi Ballester and collaborators in 2009. In this work, the authors asked 26 wine experts to evaluate a set of 18 wines that comprised six red, six white, and six rosé wines. These participants—who could not see the color of the wines (the wines were presented in dark glasses under red light)—were asked to smell the wines and to sort them in three groups. From this task (called the *sorting* task), a distance can be defined between two wines by counting

Note: Numbers in the table give the number of times two wines were not sorted together. Wines R1 to R6 are red wines, P1 to P6 are rosé wines, and W1 to W6 are white wines.

**Figure 2** Metric MDS: Experts

Note: Eigenvalues scree plot with Kaiser line. MDS = multidimensional scaling.

the number of times these two wines were *not* grouped together. Table 1 shows the distance matrix obtained from the sorting task performed by the wine experts.

Figure 2 shows the scree plot of the eigenvalues. The horizontal line in the graph is the *Kaiser* line that separates the eigenvalues larger than average (considered as reliable and warranting further investigation) from the eigenvalues smaller than average (that could be ignored at first approximation). The Kaiser line suggests that up to four dimensions could be relevant but also that the first two dimensions explain most of the variance and therefore deserve close inspection. Figure 3 shows the map obtained from these first two dimensions that together explained 45% (i.e., 33 + 12) of the variance of the data. Dimension 1 isolates the red from the rosé and white wines. Dimension 2 separates white from rosé wines. This pattern of results strongly suggests

Figure 3 Metric MDS: Experts

Figure 4 Experts (Left) and Novices (Right)

that experts do perceive wine of different colors as being different wines even when the wines are tested blindly.

Comparing Two Distance Matrices: Supplementary Projections

The authors also asked a group of 19 to sort the same wines. These novices were asked to smell the

wines and to sort them in as many groups they wanted (with the restriction that they needed to make more than one group but less than 18 groups). The results of this task are given in Table 2.

An MMDS performed on these results (see Figure 4, right panel) suggests that the novices perform in a way roughly similar to the experts, but a precise comparison is difficult to implement first because the scales of the

Note: Numbers in this table give the number of times two wines were not sorted together. Wines R1 to R6 are red wines, P1 to P6 are rosé wines, and W1 to W6 are white wines.

two graphs are not the same but also because the directions of the dimensions seem reversed (e.g., experts have their red wines on the left side of Dimension 1, novices have them on the right side). Because the experts here play the role of a reference, we need to find an optimal transformation that can fit the space of the novices into the space of the experts. There are, in fact, several methods—collectively called *Procrustes* or *Procrustean*—that can perform this task. Here we present one of these methods called *projection as supplementary elements*.

MDS: Supplementary Elements

After we have computed the MDS solution, it is possible to project supplementary or illustrative elements (also called *out of sample elements*) onto this solution. To illustrate this procedure, we will project the distance matrix from Table 2 obtained from the sorting task

performed by the novice wine tasters onto the space defined by the analysis of the sorting task by the expert wine tasters.

The number of supplementary elements is denoted by I_{sup} . For each supplementary elements, we need the values of its distances to all the I active elements. We can store these distance in an $I \times I_{\text{sup}}$ supplementary distance matrix denoted $\tilde{D}_{\text{sup}}$. The first step is to norm matrix $\tilde{D}_{\text{sup}}$ in order to make commensurable with the active distance matrix D . This step is necessary here, because the maximum distance for a sorting distance matrix is equal to the number of participants: Here for D the largest possible distance is 26 (i.e., the number of experts), whereas for $\tilde{D}_{\text{sup}}$ it is equal to 19. So, $\tilde{D}_{\text{sup}}$ is rescaled to get

$$D_{\text{sup}} = \tilde{D}_{\text{sup}} \frac{26}{19}. \quad (24)$$

After normalization of the supplementary distance matrix, the next step is to transform D_{sup} into a cross-product matrix denoted S_{sup} . This is done by first computing the difference for each supplementary column and the average distance vector and then centering the rows with the same centering matrix that was used previously to transform the distance of the active elements. Specifically, the supplementary cross-product matrix is obtained as:

$$S_{\text{sup}} = -\frac{1}{2} \Xi (D_{\text{sup}} - Dm1)^T \quad (25)$$

(where 1 is an I_{sup} by 1 vector of ones; note, also, that when $D_{\text{sup}} = D$, Equation 25 reduces to Equation 11).

The next step is to project the matrix S_{sup} onto the space defined by the analysis of the active distance matrix. We denote by F_{sup} the matrix of projection of the supplementary elements. Its computational formula is obtained by first combining Equations 15 and 13 in order to get

$$F = S^T M^{-\frac{1}{2}} U \Lambda^{-\frac{1}{2}}, \quad (26)$$

and then substituting S_{sup} for S and simplifying gives

$$F_{\text{sup}} = S_{\text{sup}}^T M^{-\frac{1}{2}} U \Lambda^{-\frac{1}{2}} = S_{\text{sup}}^T F \Lambda^{-1}. \quad (27)$$

Figure 5 displays the projection of the novices as supplementary elements in the space defined by the experts.

Analyzing Nonmetric Data

MMDS is adequate only when dealing with with real (preferably Euclidean) distances (see Togerson, 1958). In order to accommodate weaker measurements such

Figure 5 Metric MDS: Experts MDS Solution With Novices Projected as Supplementary Elements

Figure 6 Nonmetric MDS: Experts

Note: Wines R1 to R6 are red wines, P1 to P6 are rosé wines, and W1 to W6 are white wines. MDS = multidimensional scaling.

as dissimilarities, NMDS is adequate. NMDS seeks to approximate the original data by an Euclidean distance matrix that preserves the order of the original data. In this case, the order of the Euclidean distances in the map best approximates the order of the original data.

NMDS (developed by Shepard, 1966, and Kruskal, 1964) uses iterative computational approximations (mostly gradient descent) that, however, are not always guaranteed to converge. In addition, these methods need to fix a priori the dimensionality of the solution and could give different solutions for different dimensionality. Despite these potential problems, these methods provide a useful tool to graphically represent dissimilarity data. As an illustration, the sorting data of the experts were used to perform NMDS. The results, shown in Figure 6, give a configuration very similar to the MDS (which is optimal for Euclidean distances such as the sorting task distances) even though the original distances are not exactly recovered.

MULTILEVEL MODELING

Multilevel modeling (MLM) is a regression-based analytic strategy for handling nonindependent data (i.e., data that are either nested or clustered). This strategy developed as an important tool for answering research questions within the fields of public health, sociology, psychology, and education where populations of nested and clustered data are focal. When research designs examine multiple observations of individuals across a measurement, the data are referred to as *nested* or *repeated measures*. In these studies, researchers examine how participants differ from each other and how individuals vary over time. A common example of nested data are studies that use daily diary or physiological assessments with repeated measures nested under each participant. Clustered data involve a hierarchical structure, such that individuals in the same group are hypothesized to share meaningful, common characteristics that make them more similar to each other and different from other groups in the same data set. A common clustered data design might be classrooms within the same school and across different schools or individuals within a dyad (e.g., couple) or family. For example, if a researcher were interested in academic outcomes among students across school districts, students are clustered in classrooms that are clustered within schools, and these schools are clustered within districts. Observations within each of these clusters are more similar than observations from different clusters, which leads to correlated error terms. As discussed in this entry, however, most of the common MLM techniques are basic extensions of ordinary least squares (OLS) regression and are accessible to anyone with a basic working knowledge of multiple regression.

History and Advantages

Statistical analyses conducted within a MLM framework date back to the late 19th century with the work of George Airy in astronomy, but the basic specifications used today were greatly advanced in the 20th century by Ronald Fisher and Churchill Eisenhart's introduction of fixed- and random-effects modeling. A critical statistic for determining the degree of interrelatedness in one's data is the intraclass correlation coefficient (ICC). The ICC is calculated as the ratio of between-group or between-subject variance to the total

variance; therefore, the ICC ranges from 0 to 1. A high ICC suggests that the assumption of independence is violated. When the ICC is high, using traditional methods such as multiple linear regression is problematic because the interdependence in the data will yield biased results (i.e., inflating sample size), which can lead to statistically significant findings that are not based on random sampling. In addition, it is important to account for the nonindependence of the data in order to capture variation resulting from between-groups or between-subject differences after accounting for within-group or within-subject differences. Not doing so will bias these estimates (i.e., Simpson's paradox) because within-group or within-individual variation usually accounts for most of the total variance. While researchers often ask, How big does the ICC need to be to make MLM necessary? The answer should be based in theory—if the data are nested, use MLM.

Another advantage of MLM is that more traditional approaches for studying repeated measures, such as repeated measures analysis of variance (ANOVA), cannot accommodate missing or unbalanced data (e.g., classrooms with different numbers of students), leading these data to be dropped from further analysis. MLM techniques were designed to use an iterative process of model estimation by which all data can be utilized; the two most common approaches are maximum and restricted maximum likelihood estimation (both of which are discussed in this entry).

Important Distinctions

MLM is also referred to as hierarchical linear models, mixed models, general linear mixed models, latent curve growth models, variance components analysis, random coefficients models, or nested or clustered models. All of these monikers are accurate examples of MLM, but using them synonymously can lead to confusion. For instance, the software HLM, developed by Tony Bryk and Steve Raudenbush, is a proprietary statistical program for MLM, but MLM can also be conducted in other popular statistical programs including SAS, SPSS, R, as well as a host of software for analyzing structural equation models (e.g., LISREL, Mplus). MLM can also be applied to nonlinear models, such as those associated with trajectories of change and growth. Latent curve growth analysis, a structural equation modeling technique used to fit different curves associated with individual trajectories of change,

is statistically identical to regression-based MLM. Furthermore, MLM is referred to as mixed models analysis by those who view between-subjects or between-groups and within-subjects or within-groups differences as contributing to variance. Finally, variance components analysis and random coefficients models refer to variance that is assumed to be random across groups or individuals as opposed to fixed as is assumed in single-level regression.

Person-Period and Clustered Data

MLM can be used flexibly with multiple types of data structures, with person-period (nested) and clustered data being the most common types. Person-period data examine both between-individual and within-individual variation, with the latter examining how an individual varies across a measurement period using longitudinal data that examine observational targets' change over time. In a daily diary study scenario, where each diary entry or measurement (Level 1) is nested within an individual (Level 2), a researcher might be interested in examining change within an individual's daily measurements across a period of time and how changes in those daily ratings differ as a function of individual differences. Said differently, at the within-person level (Level 1), there are predictors associated with an individual's rating at any time point, but there also exist between-person (Level 2) variables that moderate the strength of that association. An assumption of MLM is that these responses are inherently related and more similar within the individual than they are across individuals (i.e., autocorrelated). Another important consideration is the number of time points needed to describe the process of change. As a line can be perfectly predicted by two points, at least three observations are needed in a linear model and at least four observations are needed in a nonlinear model in order to separate error and change.

A similar logic applies for clustered data, such as can be found in research on schools or psychological research on romantic dyads. For the latter case, it is often safe to assume that romantic partners are more similar to each other than partners in another dyad. This effect could result from being exposed to each other or the same home environment and financial circumstances, for example. Thus, persons' individual responses (Level 1) are considered nested within the dyad (Level 2). A researcher might be interested in examining individual persons' mood rating to ascertain

if variability is due to differences among persons (Level 1) as opposed to dyads (Level 2). Similar to person-period data, this example can investigate within-dyad variability at the lowest level and between-dyad variability at the highest level of the hierarchy.

The main distinction between these data structures rests in the information used to make statistical inferences. For person-period data, one can make inferences regarding variability within person responses or trajectories of change over a period of time, which may help answer questions related to the study of change. For clustered data, one can study differences among and within groups, which may help answer questions regarding programs' or interventions' effectiveness. Perhaps not surprisingly, these two structures also can be combined, for example, when multiple mood assessments are given over time (Level 1) and nested within a person (Level 2) who is embedded in a dyad (Level 3). For a three-level model, enough variability is needed at Level 1 and Level 2 to estimate separate intercepts and slopes at each level. A thorough discussion of this three-level example is beyond the scope of the present entry, but this topic is raised as an example of the flexibility and sophistication of MLM.

The Multilevel Model

This section follows the formal notation introduced by Bryk and Raudenbush, Judith Singer and John Willet, and others. A standard two-level equation for the lower and higher levels of a hierarchy that includes a predictor at Level 1 is presented first, followed by a combined equation showing the collapsed single-level model. This last step is important because depending on which software is chosen, the two-level model may require an explicit equation. It is important to note, also, that these equations are the same for any two-level person-period or clustered data set.

The two-level model in its simplest form is as follows:

$$\text{Level 1: } Y_{ij} = \beta 0_i + \beta 1_i + \varepsilon_{ij}, \quad (1)$$

where i refers to individual and j refers to time, $\beta 0_i$ is the intercept for this linear model and $\beta 1_i$ is the slope for the trajectory of change. Notice that the Level 1 equation looks almost identical to the equation used for a simple linear regression. The main differences are the error term ε_{ij} and the introduction of subscripts i and j . The error term signifies random measurement error associated with data that, contrary to the slope, deviate from linearity. Using the earlier daily diary (person-period) example, the Level-1 equation details that individual i 's rating at time j is dependent upon his or her first rating ($\beta 0_i$) and the slope of linear change

($\beta 1_i$) between Time (or Occasion) 1 and Time j (note that $\beta 1_i$ does not always represent time, but more generally represents a one-unit change from baseline in the time *varying* Level-1 predictor; the equations are identical, however). The Level-2 equation estimates the individual growth parameters of the intercept and slope for each individual by the following equations:

$$\begin{aligned} \text{Level 2: } \beta 0_i &= \gamma 00 + \zeta 0_i, \\ \beta 1_i &= \gamma 10 + \zeta 1_i, \end{aligned} \quad (2)$$

where $\zeta 0_i$ and $\zeta 1_i$ indicate that the Level-2 outcomes ($\beta 0_i$ and $\beta 1_i$, the intercept and the slope from the Level-1 model) each have a residual term that are assumed to be independent, while $\gamma 00$ represents the grand mean and $\gamma 10$ indicates the grand slope for the sample. This means that the intercept and slope are expected to vary across individuals and will deviate from the average intercept and slope of the entire sample.

By substituting in the Level-2 equations into the Level-1 equation, one can derive the collapsed model:

$$\begin{aligned} Y_{ij} &= [(\gamma 00 + \zeta 0_i) + (\gamma 10 + \zeta 1_i)] + \varepsilon_{ij}, \\ Y_{ij} &= (\gamma 00 + \gamma 10) + (\zeta 1_i + \zeta 0_i + \varepsilon_{ij}). \end{aligned} \quad (3)$$

Types of Questions Answered Using MLM

This section details the most useful and common approaches for examining multilevel data and is organized in a stepwise fashion with each consequent model adding more information and complexity.

Unconditional Means Model

This approach is analogous to a one-way ANOVA examining the random effect, or variance in means, across individuals in a person-period data set or across groups with clustered data. This model is equivalent to the model included in Equation 1 without any Level-1 predictors (i.e., the unconditional means model with only the intercept and error term). It is by running this model that one can determine the ICC and assess whether conducting a multilevel analysis is indeed warranted. Thus, the unconditional means model provides an estimate of how much between-group or between-subject and within-group or within-subject variance exists in the sample.

Means-as-Outcomes Model

This model attempts to explain the variation that occurs in individual or group means as a function of a Level-2 variable. For example, perhaps it is believed

that extroversion explains the mean differences in happiness people report across days or that the number of pop quizzes administered will predict the mean arithmetic scores for a class. By including a Level-2 predictor, it is hypothesized that the individual or group mean will be altered compared to the unconditional means model. To ascertain if this association holds true, the difference of the between-subject or between-group variance in the unconditional means is compared against the between-subject or between-group variance in the means as outcomes models. One may also examine this model if significant between-groups error variance is exhibited in the unconditional means model, as this suggests that the model should be respecified to account for this Level-2 variation.

Random Coefficient Model

As opposed to the means as outcomes model, the random coefficient model attempts to partition within-group or within-subject variability as a function of a Level-1 predictor. Following the previous example, this will yield the average intercept of happiness and the average slope of extroversion and happiness for all individuals for person-period data or the average intercept for arithmetic scores and the average slope of pop quizzes and arithmetic scores of all classrooms. In addition, this approach tests for significant differences between each individual or classroom. Average intercept and slope estimates are yielded in the output as fixed effects, while a significant p value for the variance of the slope estimate indicates that the slope varies across individuals or classrooms.

Intercepts and Slopes as Outcomes Model

The intercepts and slopes as outcome model includes both Level-1 and Level-2 predictors. This step is only completed if significant variability is accounted for by Level-2 and Level-1 predictors. As stated earlier, model testing occurs in a stepwise fashion, with this model serving as the final step.

Error Variance and Covariance: What It Is and Why It Matters

The standard MLM for assessing change can be analyzed with simple multiple regression techniques, but it is important to recognize a multilevel approach should use a specialized error term (i.e., a term that specifies why and in what way data varies). As presented in the collapsed model Equation 3, the error term in this simplified regression equation has three components: the error associated with each Level-1 equation and two

terms associated with the error around the intercept and slope, respectively. Singer was among the first to point out that these associated error terms render OLS regression analysis unfit for nested data because it assumes that the exhibited variability should approximate a multivariate normal distribution. If this were true, the mean of the residuals would be zero, the residuals would be independent of one another (they would not covary), and the population variance of the residuals would be equivalent for each measurement. Nested data sets do not adhere to these assumptions; whereas it is expected that there will be independence among individuals or groups, it is also assumed that the variance within person or group will covary and each measurement or person will be correlated to the others. Specifically, for longitudinal or person-period data, special consideration must be paid to the time dependence of the measurements for each person. There are multiple approaches that one can take when specifying how the error term should be structured in a MLM. The following is a brief and basic description of these various approaches. Notably, statistical programs have different default covariance structures. The user should consider their assumptions about how observations from the same cluster relate to each other. Specifying the correct covariance matrix allows the MLM to converge more quickly.

Partitioning Variance Between Subject or Group

Random Intercept

This approach, also called the variance components, or between-subject or between-group compound symmetric structure, is commonly used with longitudinal data where subjects are allowed to vary and each subject has a mean intercept or score that deviates from the population (or all subjects) mean. In this instance, the residual intercepts are thought to be normally distributed with a mean of zero, allowing one to assume homogeneity of variance across all observations. The default covariance structure in SAS and SPSS is random intercept.

Random Intercept and Slope

This approach is ideal for data where subjects are measured on different time schedules and allows each subject to deviate from the population both in terms of intercept and slope. Thus, each individual can have a different growth trajectory even if the hypothesis is that the population will approximate similar shapes in their growth trajectory. Using this method one can specify the residuals for the intercept and slopes to be zero or nonzero and alter the variance structures by group such that they are equal or unbalanced.

Partitioning Variance Within Subject or Group

Unstructured

As the aforementioned approaches have assumptions that can bias results, an alternative approach is to estimate the within-subject or within-group random effects. This approach assumes that each subject or group is independent with equivalent variance components. In this approach, the variance can differ at any time point, and covariance can exist between all the variance components. Of note, the use of an unstructured matrix can overfit random effects when other covariances matrices are more appropriate for their data. The default covariance structure in R is unstructured.

Within-Subject or Within-Group Compound Symmetric

This approach constrains the variance and covariance to a single value. By doing so, it is assumed that the variance is the same regardless of the time point at which the individual was measured and that the correlation between measurements or subjects will be equivalent. A subspecification of this error structure is the heterogeneous compound symmetric that dictates the variance is a single value, but the covariance between measurements or subject can differ.

Autoregressive

Perhaps the most useful error structure for longitudinal data, this approach dictates that variance is the same at all time points but the covariance decreases as measurement occasions are further apart. From a theoretical standpoint, this may not be the case in clustered data sets, but one can see how a person may make more similar ratings on Day 1 and Day 2 compared to Day 1 and Day 15. This type of error structure is common in physiological data as the correlation between points will be stronger for those measured closer in time (i.e., data with a strong lagged effect).

Model Estimation Methods

As stated earlier, MLM differs from repeated measures ANOVA analysis in that it utilizes all available data. To accomplish this, most statistical packages use a form of maximum likelihood (ML) estimation. ML estimations are favored because it is assumed they converge on population estimates, that the sampling distribution is equivalent to the known variance, and that the standard error derived from using this method is smaller

than other approaches. These advantages only apply with large samples since ML estimations are biased toward large samples and their variance estimation may become unreliable with a smaller data set. There are two types of ML techniques: full information maximum likelihood (FIML) and restricted maximum likelihood (RML/REML). FIML assumes that the dependent variable is normally distributed, and the mean is based off of the regression coefficients and the variance components. RML utilizes the least squares residuals that remain after the influence of the fixed effects are removed, and only the variance components remain. With ML algorithms, a statistic of fit is usually compared across models to understand what model best accounts for variance in the dependent variable (e.g., the deviance statistic). Multiple authors suggest that when using RML to make sure that models include the same fixed effects and only the random effects vary, since one wants to be certain the fixed effects are accounted for equivalently across models. When working with small sample sizes, RML can provide less biased estimates of the variance components.

A second class of estimation method is generalized least squares (GLS) estimation, an extension of OLS estimation. GLS estimation allows the residuals to be autocorrelated and have more dispersion of the variances but requires that the actual amount of autocorrelation and dispersion be known in the population to accurately estimate the true error in the covariance matrix. To account for this, GLS uses the estimated error covariance matrix as the true error covariance matrix and then estimates the fixed effects and associated standard errors. Another approach, iterative generalized least square, is an extension of GLS using iterations that repeatedly estimate and refit the model until either the model is converged or the maximum number of iterations has occurred. This method, again, will only work with large and relatively balanced data.

Other Applications

The applications of MLM techniques are virtually limitless. Mediation and moderation analysis are possible both within levels of the hierarchy as well as across levels. Furthermore, moderated mediation and mediated moderation principles can be applied within a MLM framework. Multilevel mediation is simplified with the Bayesian statistical approach as all effects are considered random. In addition, multilevel structural equation modeling allows the researcher to examine relationships of latent variables at different levels. This approach has become popular in recent years and can be completed in R using the *lavaan* package, which can fit a two-level SEM with random intercepts.

Learning More

MLM workshops are offered by many private companies and university-based educational programs. Books and papers, such as those listed in the Further Readings, are also informative. As mentioned, some programs are designed specifically for MLM analyses (e.g., HLM 8.0), but many of the more commonly used statistical packages (e.g., SAS and SPSS) have the same capabilities. The statistical software R can be helpful for those who are new to MLM. R is free, and the packages used for MLM have extensive documentation (see The Comprehensive R Archive Network website).

MULTIPLE BASELINE SINGLE-CASE EXPERIMENTAL DESIGN

Multiple baseline single-case experimental designs (SCEDs) provide a powerful and cost-effective framework for research aimed at exploring the effects of interventions. After first discussing SCED, this entry further explores the multiple baseline design, including its strengths and weakness. An example of SCED is also provided.

Single-Case Experimental Designs

SCEDs are unique in that they conduct experimental investigations with a single case or series of cases. A case might be an individual or a larger single unit like a business or school. These designs contrast common experimental designs (e.g., randomized controlled trials) that are conducted using large sample sizes, multiple groups (typically including a control group), and few conditions (i.e., one control condition and one experimental condition). Such large nomothetic studies are often considered the gold standard of scientific research. However, they may show differences between study groups because of a small number of skewed results; thus, statistical significance does not always translate into clinically or practically meaningful results. Furthermore, aggregating data within study groups obscures individual variability, which can be relevant to understanding the effects of an intervention on a specific person. By conducting idiographic research with small sample sizes while still allowing for experimental manipulation (e.g., randomization, control conditions) and rigorous data collection and analysis, SCED is able to provide another methodology through which to pursue research questions.

SCEDs also allow for intensive clinical observation (e.g., four children in a behavioral learning condition under frequent observation by the researcher as opposed to 100 subjects providing data at specific time points) that provides researchers with insights into individual differences that may influence results.

As such, individual differences that influence results are accounted for and the intervention can be modified or publicized with those characteristics in mind.

There are several types of SCED including multiple baseline, alternating treatment, and phase change designs. This entry focuses on a multiple baseline design, in which an intervention is staggered across behaviors, participants, or settings to demonstrate change occurs *when and only when* the intervention is introduced. Herein is the power of this design; it allows for strong causal inferences about the effect of the intervention on a designated outcome.

Multiple Baseline Design

Multiple baseline across behaviors is typically conducted within single subjects. In this design, an intervention is applied systematically across target behaviors (e.g., exploring whether a treatment increases the frequency with which a child ingests fluids, soft foods, hard foods, and chewy foods; see Nock, 2002) with each behavior serving as a control until it is intervened upon. In a between-subjects multiple baseline design, time serves as the baseline and participants are randomized to receive the intervention after differing lengths of time (e.g., a study exploring whether monetary incentives increase medication adherence for 10 adults with HIV/AIDS in which participants are randomized to waiting 2 or 4 weeks before starting to receive incentives). Whereas within-subjects designs assess multiple behavioral outcomes, between-subjects studies primarily focus on a single outcome (e.g., medication adherence). Finally, multiple baseline designs across settings may be conducted within- or between-subjects. In these designs, treatment is applied across independent situations and situations in which the intervention has not yet been introduced serve as the baseline comparator (e.g., evaluating whether an intervention reduces temper tantrums at home, at school, and in public).

Beyond choosing what kind of baseline to use (settings, behaviors, participants), there are additional considerations when designing these studies. First is the length or number of observations of each baseline. Ideally, each baseline would be stable before intervention occurs so that observed change can be attributed to the intervention. To assess stability, at least three data points are needed before intervention. However, many behaviors fluctuate over time. Therefore, it is important to monitor the data as they are being collected in order to assess the stability of the baseline. If feasible, baselines can be extended until stability is achieved. However, this is not always possible, particularly in

research studies that need to follow specific protocols. In these instances, it is key to obtain at least three observations in each baseline in order to assess stability. Second, for between-subjects designs, sample size is an important consideration. Again, it is recommended to have at least three participants per baseline length condition. This way the first participant in each condition serves as a unique experience and subsequent participants replicate (or refute) the results from the first participant. Finally, multiple baseline designs can be combined with other types of designs to create hybrid designs. For example, they are often combined with phase change designs in which multiple interventions are introduced as distinct phases throughout the study.

Data Analysis

Data analysis for SCED is continually advancing. However, visual inspection has long been, and still is, the primary mode of data analysis for this design. To conduct visual inspection analyses, data are plotted graphically with lines connecting the data points within each phase (i.e., baseline, intervention), and then are visually assessed for change across study phases. Changes in level (i.e., average) across phases indicate the magnitude of intervention effects, and changes in slope indicate the rate of change. Stable behavior, or the lack of slope in the data, would indicate that the targeted behavior neither increased nor decreased over time. As Alan E. Kazdin (2011) indicated, visual inspection is considered a conservative approach to data analysis, as it typically provides high accuracy and reliable conclusions across raters. This analysis can be supplemented by intensive clinical observation in which the researcher's observations of the subject can aid in data interpretation (e.g., knowing a participant lost their job could help explain a temporary increase in a previously decreasing behavior).

Beyond visual inspection, many statistical analyses can be used to analyze data from multiple baseline SCED. An important consideration in these analyses is the autocorrelation present in SCED data. Thus, it is important to employ statistical procedures that can take this into account. Some of the most commonly used analyses are different metrics of effect sizes (e.g., percent of nonoverlapping data, modified Hedges' *g*). In addition, reliable change indices can be used to demonstrate change on a specific outcome measure if it is significant above and beyond the fluctuation that occurs with imprecise self-report measurement tools (which are often used in SCED). Finally, recent statistical advances have begun to apply time series analyses to some SCED data. When data are collected daily, or

multiple times per day, it is possible to conduct such analyses.

Strengths and Weaknesses

As with any research design, there are strengths and weaknesses to consider with regard to multiple baseline SCED. First, there are several practical strengths to this methodology. These designs require fewer participants than traditional nomothetic research studies (e.g., randomized controlled trials), thus making them time- and cost-effective study designs. Second, this design is ideal when removing an intervention is not feasible or ethical. Other types of SCED involve introducing and removing an intervention to demonstrate the causal relationship between the intervention and a behavior. However, this is often unfeasible when the intervention involves learning a new skill because the skill can't be "unlearned." In addition, when intervening on dangerous behaviors (e.g., self-harm), removing an effective intervention is considered unethical. Therefore, multiple baseline designs provide a way to demonstrate causality without removing an effective intervention. Third, a notable strength of SCED is internal validity. In SCED, each participant serves as their own control. Thus, each participant is a self-contained, unique experiment. In this way, SCED allows researchers to draw causal inferences regarding the effects of an intervention or environmental manipulation on emotions, behaviors, and other psychological processes. Replication of results across participants provides external validity. Third, data collection in SCED occurs frequently (typically daily or weekly) providing an idiographic evaluation of intrasubject variability and change over time. In treatment studies, this allows for flexible interventions that are delivered based on a patient's response to the treatment. Taken together, these strengths make SCED ideal for preliminary studies of novel treatments or conditions as well as for studies designed to understand the effect of specific intervention components.

A point of weakness of this design can be external validity. While replication of results across participants provides preliminary external validity, these research designs do rely on small sample sizes. Thus, it is always a possibility that the participants in a given study are not representative of the larger patient population and the results of a SCED study will not generalize. In addition, for studies that rely on a single person to perform the interventions, it is also possible there is something unique about this individual that contributed to the study's results and limits generalizability. Careful consideration when designing a SCED, such as having

multiple interventionists and heterogeneous participants, can help reduce potential challenges to external validity.

Example of SCEDs

To demonstrate the application of SCED to novel research domains, the following example of a SCED examining the effects of guided mindfulness for emotion dysregulation in misophonia is presented. Misophonia is a sound intolerance condition characterized by heightened physiological arousal and negative emotional reactivity. Individuals with misophonia experience a range of emotions in response to trigger sounds including anger, disgust, and anxiety. Therefore, a treatment for misophonia must be able to address a range of dysregulated emotions.

Because of the limited extant literature on misophonia, there is a need to conduct preliminary investigation of treatments for this condition before pursuing large-scale treatment studies in order to identify promising treatment strategies. One such intervention is mindfulness. Mindfulness trains individuals to be intentionally aware of present moment experiences in a nonjudgmental manner. Thus, mindfulness may be uniquely suited for the treatment of misophonia in providing techniques for attenuating strong emotions and redirecting attention by cultivating the ability to stay in or return to the present moment. Early treatment studies can benefit from a large number of data points, controlled variability in the data, and an emphasis on change at the individual level rather than at group level. SCED lends a level of detail and precision to analyze the mechanisms contributing to change over time that a larger scale intervention study may not be able to.

A study looking to explore the effects of mindfulness on emotion regulation for adults with misophonia could employ a multiple baseline SCED across participants that begins by assessing the sample's preintervention characteristics and then staggers the implementation of the mindfulness intervention. Participants could be randomized to a 2- or 4-week baseline period in which they complete assessments of the target outcome (emotion regulation) and no intervention is applied; they would then receive six sessions of the mindfulness intervention. This design allows for both within- and between-subject comparisons. For each participant, if changes in emotion regulation occur when and only when the mindfulness intervention is introduced, we can infer the intervention impacts this outcome. If significant changes occur across participants, we may infer that the treatment

mechanisms in one or more of our mindfulness conditions were effective. Furthermore, the staggered initiation of the interventions following a baseline period helps us to evaluate if the detected changes in emotion regulation over time can indeed be attributed to the mindfulness intervention.

Final Thoughts

Multiple baseline SCED, an idiographic methodology in which data are collected frequently from each subject, provides strong internal validity because each participant serves as their own control. Replication of effects across participants provides preliminary external validity. The use of multiple baselines (either across behaviors, participants, or settings) and systematic, staggered application of interventions across them allows for strong causal inferences about the effects of an intervention on target behaviors.

MULTIPLE CASE STUDY

Multiple case study involves in-depth investigation of two or more bounded units or instances (“cases”) of a particular program, phenomenon, or issue. Cases are analyzed individually and collectively to reveal similarities, differences, and patterns in how the phenomenon manifests or operates in different real-world contexts. Multiple case studies are also referred to as *collective case studies*, *cross-case studies*, and *multisite case studies*. This entry presents a description of multiple case study, considerations for using this design, and examples.

Overview

Multiple case study focuses on the bounded case as the unit of analysis. A case can be an individual, group of people, organization, community, process, or policy. Cases are bounded by parameters that establish each case as a distinct entity, such as a specific place and time. For example, a particular school or neighborhood could constitute a case; however, the concepts of “education” or “community” could not. In a multiple case study design, several bounded cases are analyzed to collectively foster a richer, more detailed understanding of a phenomenon than examining a single case would provide. For example, a researcher investigating the use of a new educational technology might select three schools that are implementing the technology in different communities to illuminate how the technology supports and/or constrains learning in a variety of contexts. By examining the similarities and differences across the three schools, the researcher would gain a richer understanding than would be possible by studying the technology in a single school context.

Multiple case study involves the collection and analysis of multiple forms of data from multiple sources, often over an extended period of time, to produce detailed, descriptive findings. Rather than focusing on one or two variables, researchers examine multiple aspects of the phenomenon, interaction among

them, and their relationship with the broader context. This supports investigation of complex phenomena in context. Data collection and analysis are repeated sequentially for each case. A detailed, “thick” description is developed for each individual case and within-case themes are identified. Then, cross-case analysis is conducted to identify patterns of similarity and dissimilarity that transcend individual cases. Findings from each case are compared, rather than pooled. Robert Yin describes this process as following the logic of replication, which is similar to experimental research in that an experiment is repeated multiple times and results are compared.

In the educational technology example presented earlier, the researcher would first examine each school as an individual case and create detailed portraits that illustrate how the technology is implemented, how it supports and/or constrains learning, and the contextual factors that influence its adoption and use. Then, the researcher would conduct cross-case comparisons to reveal commonalities and differences across the schools, illuminating how the technology is used and operates in different contexts and conditions. Multiple case study would enable the researcher to understand the technology differently and more fully than investigation of a single school context.

Considerations for Conducting Multiple Case Studies

The decision to use a multiple case study is driven by the research questions. The design is well-suited to investigating questions about complex phenomena that are fundamentally intertwined with context. As a result, multiple case study is particularly relevant in applied areas of inquiry such as education, social work, program evaluation, and policy research. The design is not appropriate for questions that focus on one or two variables, the relationship between variables without consideration of context, or the prevalence or frequency of a phenomenon. Multiple case study is also not suitable when investigating very unique cases, as the researcher is less likely to identify multiple instances.

The research process begins by establishing a rationale for case selection. Cases are not intended to be representative of a larger population; instead, they are chosen for their potential to provide rich, holistic description of the phenomenon in its real-life context. Typically, the researcher selects cases that are relevant to the phenomenon of interest, reflect a diversity of contexts, and provide ample access and opportunity for in-depth examination. A defensible selection rationale can help to address the critique that case selection may not be sufficiently systematic and can be influenced by

researchers’ preferences. A maximum of four to five cases is recommended to ensure sufficient depth of analysis.

Data collection is extensive and draws on multiple methods, with the aim of providing a detailed, multi-dimensional portrayal of the phenomenon. Methods choices are driven by the research questions. Multiple case study often involves observation, interviews, and document analysis, which yield qualitative data, and may also incorporate methods that produce quantitative data, such as surveys. Data collection methods and processes are repeated for each case. Working sequentially, rather than gathering data from more than one case at the same time, can help researchers manage the large amount of data that is produced and ensure that sufficient time and resources are allocated for each case.

Findings are reported in the form of detailed, vivid descriptions of individual cases, as well as analysis of the themes that emerged from the cross-case analysis. Multiple case study aims to embrace, rather than reduce, complexity and produce specific, contextualized findings. As a result, reporting is detailed and focused on the particular. Researchers should consider readability, however, as overly detailed, highly specific findings can be difficult for readers to understand and interpret. Multiple case study can also be critiqued because it does not support generalization of findings beyond the cases that are examined. Instead, reporting aims to deepen the readers’ understanding through vicarious experience of the cases, allowing the reader to make interpretations and applications to other cases and contexts.

Examples

In 2011, Wendy Bray reported a multiple case study of four third-grade teachers that employed observation, interviews, and surveys to investigate error-handling practices during mathematics instruction. Cross-case analysis revealed how teachers’ knowledge and beliefs influenced their error-handling practices. Robert Stake provided many examples of multiple case studies in his 2006 book *Multiple Case Study Analysis*, including one of an early childhood education program implemented in 30 countries. Stake presented three individual cases from different countries and outlined the process of cross-case analysis used to evaluate the program overall.

MULTIPLE COMPARISON TESTS

Many research projects involve testing multiple research hypotheses. These research hypotheses could be evaluated using comparisons of means, bivariate correlations, regressions, and so forth, and in fact most studies consist of a mixture of different types of test statistics. An important consideration when conducting multiple tests of significance is how to deal with the increased likelihood (relative to conducting a single test of significance) of falsely declaring one (or more) hypotheses statistically significant, titled the *multiple comparisons problem*. This multiple comparisons problem is especially relevant to the topic of research design because the issues associated with the multiple comparisons problem relate directly to designing studies (i.e., number and nature of variables to include) and deriving a data analysis strategy for the study. This entry introduces the multiple comparisons problem and discusses some of the strategies that have been proposed for dealing with it.

The Multiple Comparisons Problem

To help clarify the multiple comparisons problem, imagine a soldier who needed to cross fields containing land mines in order to obtain supplies. It is clear that the more fields the individual crosses, the greater the probability that he or she will activate a land mine; likewise, researchers conducting many tests of significance have an increased chance of erroneously finding tests significant. It is important to note that although the issue of multiple hypothesis tests has been labeled the multiple comparisons problem, most likely because a lot of the research on multiple comparisons has come within the framework of mean comparisons, it applies to any situation in which multiple tests of significance are being performed.

Imagine that a researcher is interested in determining whether overall course ratings differ for lecture, seminar, or computer-mediated instruction formats. In this type of experiment, researchers are often interested in whether significant differences exist between any pair of formats, for example, do the ratings of students in lecture-format classes differ from the ratings of students in seminar-format classes. The multiple comparisons problem in this situation is that in order to compare each format in a pairwise manner, three tests of significance need to be conducted (i.e., comparing the means of lecture vs. seminar, lecture vs. computer-mediated, and seminar vs. computer-mediated instruction formats). There are numerous ways of addressing the multiple comparisons problem and dealing with the increased likelihood of falsely declaring tests significant.

Common Multiple Testing Situations

There are many different settings in which researchers conduct null hypothesis testing, and the following are just a few of the more common settings in which multiplicity issues arise: (a) conducting pairwise and/or complex contrasts in a linear model with categorical variables; (b) conducting multiple main effect and interaction tests in a factorial analysis of variance (ANOVA) or multiple regression setting; (c) analyzing multiple simple effect, interaction contrast, or simple slope tests when analyzing interactions in linear models; (d) analyzing multiple univariate ANOVAs after a significant multivariate ANOVA (MANOVA); (e) analyzing multiple correlation coefficients; (f) assessing the significance of multiple factor loadings or factor correlations in factor analysis; (g) analyzing multiple dependent variables separately in linear models; (h) evaluating multiple parameters simultaneously in a structural equation model; and (i) analyzing multiple brain voxels for stimulation in functional magnetic resonance imaging research. Further, as stated previously, most studies involve a mixture of many different types of test statistics.

An important factor in understanding the multiple comparisons problem is understanding the different ways in which a researcher can “group” his or her tests of significance. For example, suppose, in the study looking at whether student ratings differ across instruction formats, that there was also another independent variable, the sex of the instructor. There would now be two “main effect” variables (instruction format and sex of the instructor) and potentially an interaction between instruction format and sex of the instructor. The researcher might want to group the

hypotheses tested under each of the main effect (e.g., pairwise comparisons) and interaction (e.g., simple effect tests) hypotheses into separate “families” (groups of related hypotheses) that are considered simultaneously in the decision process. Therefore, control of the Type I error (error of rejecting a true null hypothesis) rate might be imposed separately for each family, or in other words, the Type I error rate for each of the main effect and interaction families is maintained at α . On the other hand, the researcher may prefer to treat the entire set of tests for all main effects and interactions as one family, depending on the nature of the analyses and the way in which inferences regarding the results will be made. The point is that when researchers conduct multiple tests of significance, they must make important decisions about how these tests are related, and these decisions will directly affect the power and Type I error rates for both the individual tests and for the group of tests conducted in the study.

Type I Error Control

Researchers testing multiple hypotheses, each with a specified Type I error probability (α), risk an increase in the overall probability of committing a Type I error as the number of tests increases. In some cases, it is very important to control for Type I errors. For example, if the goal of the researcher comparing the three classroom instruction formats described earlier was to identify the most effective instruction method that would then be adopted in schools, it would be important to ensure that a method was not selected as superior by chance (i.e., a Type I error). On the other hand, if the goal of the research was simply to identify the best classroom formats for future research, the risks associated with Type I errors would be reduced, whereas the risk of not identifying a possibly superior method (i.e., a Type II error) would be increased. When many hypotheses are being tested, researchers must specify not only the level of significance, but also the unit of analysis over which Type I error control will be applied. For example, the researcher comparing the lecture, seminar, and computer-mediated instruction formats must determine how Type I error control will be imposed over the three pairwise tests. If the probability of committing a Type I error is set at α for each comparison, then the probability that at least one Type I error is committed over all three pairwise comparisons can be much higher than α . On the other hand, if the probability of committing a Type I error is set at α for all tests conducted, then the probability of committing a Type I error for each of the comparisons can be much

lower than α . The conclusions of an experiment can be greatly affected by the unit of analysis over which Type I error control is imposed.

Units of Analysis

Several different units of analysis (i.e., error rates) have been proposed in the multiple comparison literature. The majority of the discussion has focused on the per-test and familywise error rates, although other error rates, such as the *false discovery rate*, have recently been proposed.

Per-Test Error Rate

Controlling the per-test error rate (α_{PT}) involves simply setting the α level for each test (α_T) equal to the global α level. Recommendations for controlling α_{PT} center on a few simple but convincing arguments. First, it can be argued that the natural unit of analysis is the test. In other words, each test should be considered independent of how many other tests are being conducted as part of that specific analysis or that particular study or, for that matter, how many tests the researcher might conduct over his or her career. Second, real differences between treatment groups are more likely with a greater number of treatment groups. Therefore, emphasis in experiments should be not on controlling for unlikely Type I errors but on obtaining the most power for detecting even small differences between treatments. The third argument is the issue of (in)consistency. With more conservative error rates, different conclusions can be found regarding the same hypothesis, even if the test statistics are identical, because the per-test α level depends on the number of comparisons being made. Last, one of the primary advantages of α_{PT} control is convenience. Each of the tests is evaluated with any appropriate test statistic and compared to an α -level critical value.

The primary disadvantage of α_{PT} control is that the probability of making at least one Type I error increases as the number of tests increases. The actual increase in the probability depends, among other factors, on the degree of correlation among the tests. For independent tests, the probability of a Type I error with T tests is $1 - (1 - \alpha)^T$, whereas for nonindependent tests (e.g., all pairwise comparisons, multiple path coefficients in structural equation modeling), the probability of a Type I error is less than $1 - (1 - \alpha)^T$. In general, the more tests that a researcher conducts in his or her experiment, the more likely it is that one (or more) will be significant simply by chance.

Familywise Error Rate

The familywise error rate (α_{FW}) is defined as the probability of falsely rejecting one or more hypotheses in a family of hypotheses. Controlling α_{FW} is recommended when some effects are likely to be nonsignificant; when the researcher is prepared to perform many tests of significance in order to find a significant result; when the researcher's analysis is exploratory, yet he or she still wants to be confident that a significant result is real; and when replication of the experiment is unlikely.

Although many multiple comparison procedures purport to control α_{FW} , procedures are said to provide strong α_{FW} control if α_{FW} is maintained at approximately α when all population means are equal (complete null) and when the complete null is not true but multiple subsets of the population means are equal (partial nulls). Procedures that control α_{FW} for the complete null, but not for partial nulls, provide weak α_{FW} control.

The main advantage of α_{FW} control is that the probability of making a Type I error does not increase with the number of comparisons conducted in the experiment. One of the main disadvantages of procedures that control α_{FW} is that α_T decreases, often substantially, as the number of tests increases. Therefore, procedures that control α_{FW} have reduced power for detecting treatment effects when there are many comparisons, increasing the potential for inconsistent results between experiments.

False Discovery Rate

The false discovery rate represents a compromise between strict α_{FW} control and liberal α_{PT} control. Specifically, the false discovery rate (α_{FDR}) is defined as the expected ratio (Q) of the number of erroneous rejections (V) to the total number of rejections ($R = V + S$), where S represents the number of true rejections. Therefore, $E(Q) = E(V / [V + S]) = E(V / R)$.

If all null hypotheses are true, $\alpha_{FDR} = \alpha_{FW}$. On the other hand, if some null hypotheses are false, $\alpha_{FDR} \leq \alpha_{FW}$, resulting in weak control of α_{FW} . As a result, any procedure that controls α_{FW} also controls α_{FDR} , but procedures that control α_{FDR} can be much more powerful than those that control α_{FW} , especially when a large number of tests are performed, and do not entirely dismiss the multiplicity issue (as with α_{PT} control). Although some researchers recommend exclusive use of α_{FDR} control, it is often recommended that α_{FDR} control be reserved for exploratory research, nonsimultaneous inference (e.g., if one had multiple dependent variables and separate inferences would be

made for each), and very large family sizes (e.g., as in an investigation of potential activation of thousands of brain voxels in functional magnetic resonance imaging).

Multiple Comparison Procedures

This section introduces some of the multiple comparison procedures that are available for controlling α_{FW} and α_{FDR} . Recall that no multiple comparison procedure is necessary for controlling α_{PT} as the α level for each test is equal to the global α level and can therefore be used seamlessly with any test statistic. It is important to note that the procedures introduced here are only a small subset of the procedures that are available, and for the procedures that are presented, specific details are not provided. Please see specific sections of the encyclopedia for details on these procedures.

Familywise Error Controlling Procedures for Any Multiple Testing Environment

Bonferroni

This simple-to-use procedure sets $\alpha_T = \alpha/T$, where T represents the number of tests being performed. The important assumption of the Bonferroni procedure is that the tests being conducted are independent. When this assumption is violated (and it commonly is), the procedure will be too conservative.

Dunn-Šidák

The Dunn-Šidák procedure is a more powerful version of the original Bonferroni procedure. With the Dunn-Šidák procedure, $\alpha_T = 1 - (1 - \alpha)^{1/T}$.

Holm

Sture Holm proposed a sequential modification of the original Bonferroni procedure that can be substantially more powerful than the Bonferroni or Dunn-Šidák procedures.

Hochberg

Yosef Hochberg proposed a modified segue to Bonferroni procedure that combined Simes's inequality with Holm's testing procedure to create a multiple comparison procedure that can be more powerful and simpler than the Holm procedure.

Familywise Error Controlling Procedures for Pairwise Multiple Comparison Tests

Tukey

John Tukey proposed the honestly significant difference procedure, which accounts for dependencies among the pairwise comparisons and is maximally powerful for simultaneous testing of all pairwise comparisons.

Hayter

Anthony Hayter proposed a modification to Fisher's least significant difference procedure that would provide strong control over α_{FW} .

REGWQ

Ryan proposed a modification to the Newman-Keuls procedure that ensures that α_{FW} is maintained at α , even in the presence of multiple partial null hypotheses. Ryan's original procedure became known as the REGWQ after modifications to the procedure by Einot, Gabriel, and Welsch.

False Discovery Rate-Controlling Procedures for Any Multiple Testing Environment

FDR-BH

Yoav Benjamini and Hochberg proposed the original procedure for controlling the α_{FDR} , which is a sequential modified Bonferroni procedure.

FDR-BY

Benjamini and Daniel Yekutieli proposed a modified α_{FDR} controlling procedure that would maintain $\alpha_{FDR} = \alpha$ under any dependency structure among the tests.

When multiple tests of significance are performed, the best form of Type I error control depends on the nature and goals of the research. The practical implications associated with the statistical conclusions of the research should take precedence when selecting a form of Type I error control.

MULTIPLE COMPARISON PROCEDURES WITH MODELING TECHNIQUES

Combining multiple comparison procedures (MCP) with modeling techniques (Mod) results in a hybrid approach, MCP-Mod, that accounts for model uncertainty. Many applications in medicine, epidemiology, and psychology rely on modeling the nonlinear relationship between a covariate (e.g., increasing dose levels of a new drug) and an outcome variable (e.g., blood pressure). The parametric form of the underlying nonlinear relationship is typically unknown in practice, leading to model uncertainty. A common approach is to select a working model based on the observed data. However, it is well known that such approaches do not account for model uncertainty and may lead to undesirable effects due to data dredging and overfitting, such as biased treatment effect estimates and overoptimistic inferences. This entry reviews the MCP-Mod approach, provides an example, and discusses extensions to this approach.

The MCP-Mod Approach

Originally developed in 2005 for clinical dose finding studies, MCP-Mod is an efficient statistical approach for model-based design and analysis of dose-response studies that acknowledges model uncertainty through the following steps:

1. testing for the presence of a trend (e.g., decreasing blood pressure with increasing doses),

2. selecting the best model for the observed data out of a prespecified set of candidate models, and
3. estimating relevant features via modeling (e.g., the dose-response curve or a target dose achieving a practically relevant effect).

At the design stage of a study, the research team decides on the core aspects, such as the outcome variable and the study population, as in any other study. Specific to MCP-Mod is the need to prespecify a candidate set of plausible dose-response models, through discussions within the research team, based on existing information. These models can be linear or nonlinear, monotone or U-shaped (see the next section for an example). This candidate set then gives rise to a set of optimal contrast coefficients used to test for the presence of a significant trend. In case of large model uncertainty, this candidate set should cover a diverse set of plausible regression models. Besides choosing the individual candidate regression models, the team also needs to specify initial guesses for the model parameters, called *guesstimates*. For example, these guesstimates can be derived from some initial knowledge of the expected percentage of the maximum response for a given dose. After specifying the guesstimates, each regression model produces a specific dose-response shape, which can then be used to calculate the expected

mean responses at each dose under investigation. Sample size calculations at the design stage are then based either on power considerations (e.g., to achieve a prespecified probability of establishing a trend based on the stipulated mean responses [Step 1] or on a pre-specified precision for the estimation [Step 3]).

At the analysis stage of a study, the research team performs both the MCP and the Mod step. The MCP step focuses on establishing evidence for a statistically significant trend (e.g., detecting a dose-response signal for the outcome variable and study population being investigated). This step will typically be performed using an efficient MCP (multiple contrast test), adjusting for the fact that multiple candidate dose-response models are being considered. If a statistically significant trend has been established, the research team proceeds with determining a reference set of significant regression models by discarding the nonsignificant models from the initial candidate set. Out of this reference set, relevant features are estimated using either model selection or model averaging techniques (e.g., the dose-response model or target doses that meet certain response thresholds).

Example

We use the biom data set from the DoseFinding package in R to illustrate the MCP-Mod methodology. The data set contains a total of 100 individuals being

Figure 1 Plot of Candidate Models Specified in R Code

randomized to either placebo or one of four active doses coded as 0.05, 0.20, 0.60, and 1, with 20 per group. We assume the response variable to be normally distributed and larger values indicate a better outcome.

The first step of MCP-Mod is to identify the candidate model set. In practice, identifying the candidate model set is the result of a discussion within the research team, using all available information and plausibility arguments. Here, we select the candidate set to include two concave shapes being the linear-in-log and the quadratic shape, a convex shape using an exponential, and the linear shape. The shapes can be specified and visualized with DoseFinding using the following R code (see Figure 1):

```
> ## load DoseFinding package
> library(DoseFinding)
> doses <- c(0,0.05,0.2,0.6,1) ##
  doses in the study
> ## define candidate set
> candMod <- Mods(linlog=NULL,
  linear=NULL, quadratic=-0.83,
  exponential=0.4, doses=doses)
> ## plot candidate set
> plot(candMod, placEff = 0, maxEff = 1)
```

After the study is completed and data have been obtained, one can use the MCPMod function to analyze the data. To perform the target dose estimation, the

inputs for the function are the dose and response values, the candidate models, and the response threshold. In this example, we estimate the smallest dose that achieves an improvement 0.4 on top of the placebo response. To run the MCP-Mod analysis, the following code can be used:

```
> data(biom) ## load data
> ## fit MCPMod
> MMfit <- MCPMod(dose, resp, models =
  candMod, data=biom, Delta = 0.4)
> MMfit
MCPMod
```

Multiple Contrast Test:

	t-Stat	adj-p
linlog	3.411	0.00104
quadratic	3.202	0.00206
linear	2.972	0.00442
exponential	2.418	0.02010

...

Selected model (AIC): linlog

Estimated TD, Delta=0.4

	linlog	linear	quadratic	exponential
	0.1455	0.7161	0.2813	0.7843

One can observe that the linear-in-log shape has the largest contrast test statistic but also all other

Figure 2 Plot of Selected Linear-in-Log Dose-Response Model With Pointwise 95% Confidence Intervals as Specified in R Code

dose–response shapes are significant. Hence, all dose–response models are used in the model estimation step, with the estimated model parameters shown in the output. The linear-in-log model is ultimately selected when applying the Akaike information criterion (AIC) for the model selection to determine a single dose–response model out of the selected model set. The estimated target doses, giving an improvement of 0.4 over placebo under the different models, are shown in the last line of the output. Concluding the MCP-Mod analysis, a graphical depiction of the fitted dose–response model can be obtained via (see Figure 2):

```
## plot resulting model-fit
plot(MMfit$mods$linlog, CI=TRUE,
plotData = "meansCI", lwd=2)
```

Extensions

In practice, the modeling situation and study design may be more complex than described in this entry. For example, the response variable might be a count, binary, or time-to-event variable instead of being normally distributed. In addition, the final analysis usually has to be adjusted for relevant covariates (e.g., region, age) and individual measurements are often recorded over time (necessitating the use of longitudinal models). Extensions of the original MCP-Mod approach are available such that the core ideas remain applicable in these situations.

The original MCP-Mod approach has been subject to various other extensions. For example, response-adaptive extensions of MCP-Mod with one or multiple interim analyses are possible and often advisable as they may result in power gains to detect a significant trend or in higher precision to estimate the regression curve. Conversely, such designs also allow the possibility to stop a study early in case of lack of efficacy. Several authors have extended MCP-Mod using likelihood ratio tests that do not rely on the specification of guesstimates, which simplifies the use of MCP-Mod in practice. Further extensions of MCP-Mod include the use of Bayesian methods for estimating or selecting the dose–response curve from a sparse dose design as well as its application to joint efficacy-safety modeling and subgroup analyses.

MULTIPLE GROUP STRUCTURAL EQUATION MODELING

Multiple group structural equation modeling (MG-SEM) is a structural equation model (SEM) analysis extended to more than one set of data. The groupings may be preexisting (e.g., gender or race), or they may be imposed (e.g., assignment to treatment or control group, or groupings based on other measured variables). Recall, SEM is a form of latent variable analysis. A path analysis is an examination of regression equations in a (potentially complex) network of interconnected relationships. An SEM analysis is different from a path analysis in that the latter uses only manifest (or directly observable) variables, whereas the former allows for latent (or unobserved) variables to be modeled. Consequently, many SEM analyses involve both a structural model (the path model, if you will) and a measurement model. The measurement model is the means by which the influence of the latent variables on the overall relationship among all the data is parsed out and identified. This entry first reviews a basic example of model parameter equivalence (multiple regression). Next, the concept of measurement model equivalence is addressed. Finally, the complete stages of an MG-SEM analysis are presented.

To better understand MG-SEM, it is useful to review how group comparisons can be made in the multiple regression framework. As a quick review, consider a multiple regression model predicting a scalar dependent variable (e.g., math performance). If the multiple regression model includes a dichotomous independent variable (a grouping variable such as gender), a scalar independent variable (such as math anxiety), and the interaction of these two variables, then one can assess if the two separate bivariate regression models for each group are the same or not. That is, are the slopes and intercepts for each bivariate model the same for each group. In particular, the bivariate model would predict

math performance from math anxiety. Obtaining the bivariate regression for each group would result in two different slopes. However, by running the multiple regression model with the three predictors (one dichotomous variable, one scalar variable, and the interaction), the interaction term can serve as a test as to whether or not the slopes are the same between the two groups. If they are the same (or if they are at least not statistically significantly different), this suggests that the slope part of the model is the same for the two groups. This is what might be referred to as model equivalence between the two groups.

With this idea of model equivalence in mind, the overarching importance of MG-SEM can be explained. As an SEM analysis can involve a structural part (the path model), it is reasonable to ask if the same model was run for two (or more) different groups, would any part (if not all) of the model be the same for the two groups. For each part of the model that is the same, it is possible to constrain the parameters being estimated in the model to be equivalent across the groups. (This is not dissimilar to the aforementioned multiple regression example when an analysis of covariance [ANCOVA] model is being run; in the ANCOVA model, the slopes for the different groups are constrained to be the same.)

However, there is an additional complication with MG-SEM analyses. The measurement model also needs to be examined to determine if it is equivalent across the different groups. One common use of MG-SEM is to test measurement model invariance between groups. An SEM that consists only of the measurement component (e.g., no structural or path model) can be viewed as a confirmatory factor analytic (CFA) model. A CFA model can be used to determine if a measurement instrument is indeed measuring the intended latent variable constructs (or factors) under examination. More importantly, in the construction of a measurement instrument, it is important to show cross-population validity; that is, it is necessary to show that the same instrument measures the same constructs for different populations. With an MG-SEM, one can show that the parameters of the CFA model are the same across the different groups under examination. If this can be achieved, this adds strength to the argument that the measurement instrument is indeed valid.

One of the complexities of a full MG-SEM analysis is that one must demonstrate that the measurement model component of the full SEM model is not group invariant, while the structural (path) model component may or may not be group invariant. That is to say, it is necessary to first confirm that the same thing is being measured before asking if there is a difference between relationships of those variables that were to have been

measured. As a result of this additional level of complexity, an MG-SEM analysis often involves a hierarchy of levels of equivalence. First, the measurement model is examined for configural equivalence (i.e., is the overall “shape” or “structure” of the model the same between the different groups). Metric equivalence is used to determine if the factor loadings for the latent variables are equivalent across groups. Scalar equivalence is next used to determine if the thresholds and/or intercepts for the measurement models are equivalent across groups. The measurement structural equivalence is examined to determine if the correlations between the latent factors are the same for the different groups. Finally, a group comparison analysis is conducted to see if the latent variable group means are the same or not.

If the researchers believe that there are group differences in the structural (path) model, then the last two equivalence tests will most likely fail to show equal parameters for all of the groups. In this case, the last two tests of equivalence listed previously are replaced with the test of structural equivalence. In this step, the parameters of the path model between the latent variables are assessed for group equivalence. When equivalence is not demonstrated, there is evidence to suggest that the relationship of the variables under consideration change from one group to another.

MULTIPLE REGRESSION

Multiple regression is a general and flexible statistical method for analyzing associations between two or more independent variables and a single dependent variable. As a general statistical technique, multiple regression can be employed to predict values of a particular variable based on knowledge of its association with known values of other variables, and it can be

used to test scientific hypotheses about whether and to what extent certain independent variables explain variation in a dependent variable of interest. As a flexible statistical method, multiple regression can be used to test associations among continuous as well as categorical variables, and it can be used to test associations between individual independent variables and a dependent variable, as well as interactions among multiple independent variables and a dependent variable. In this entry, different approaches to the use of multiple regression are presented, along with explanations of the more commonly used statistics in multiple regression, methods of conducting multiple regression analysis, and the assumptions of multiple regression.

Approaches to Using Multiple Regression

Prediction

One common application of multiple regression is for predicting values of a particular dependent variable based on knowledge of its association with certain independent variables. In this context, the independent variables are commonly referred to as *predictor* variables and the dependent variable is characterized as the *criterion* variable. In applied settings, it is often desirable for one to be able to predict a score on a criterion variable by using information that is available in certain predictor variables. For example, in the life insurance industry, actuarial scientists use complex regression models to predict, on the basis of certain predictor variables, how long a person will live. In scholastic settings, college and university admissions offices will use predictors such as high school grade point average (GPA) and ACT scores to predict an applicant's college GPA, even before he or she has entered the university.

Multiple regression is most commonly used to predict values of a criterion variable based on *linear* associations with predictor variables. A brief example using simple regression easily illustrates how this works. Assume that a horticulturist developed a new hybrid maple tree that grows exactly 2 feet for every year that it is alive. If the height of the tree was the criterion variable and the age of the tree was the predictor variable, one could accurately describe the relationship between the age and height of the tree with the formula for a straight line, which is also the formula for a simple regression equation:

$$Y = bX + a,$$

where Y is the value of the dependent, or criterion, variable; X is the value of the independent, or predictor, variable; b is a regression coefficient that describes the slope of the line; and a is the Y intercept. The Y

intercept is the value of Y when X is 0. Returning to the hybrid tree example, the exact relationship between the tree's age and height could be described as follows:

$$\text{height} = 2(\text{age in years}) + 0$$

Notice that the Y intercept is 0 in this case because at 0 years of age, the tree has 0 height. At that point, it is just seed in the ground. It is clear how knowledge of the relationship between the tree's age and height could be used to easily predict the height of any given tree by just knowing what its age is. A 5-year-old tree will be 10 feet tall, an 8-year-old tree will be 16 feet tall, and so on.

At this point two important issues must be considered. First, virtually any time one is working with variables from people, animals, plants, and so forth, there are no perfect linear associations. Sometimes students with high ACT scores do poorly in college whereas some students with low ACT scores do well in college. This shows how there can always be some *error* when one uses regression to predict values on a criterion variable. The stronger the association between the predictor and criterion variable, the less error there will be in that prediction. Accordingly, regression is based on the *line of best fit*, which is simply the line that will best describe or capture the relationship between X and Y by minimizing the extent to which any data points fall off that line.

A college admissions committee wants to be able to predict the graduating GPA of the students whom they admit. The ACT score is useful for this, but as noted above, it does not have a perfect association with college GPA, so there is some error in that prediction. This is where multiple regression becomes very useful. By taking into account the association of additional predictor variables with college GPA, one can further minimize the error in predicting college GPA. For example, the admissions committee might also collect information on high school GPA and use that in conjunction with the ACT score to predict college GPA. In this case, the regression equation would be

$$Y' = b_1X_1 + b_2X_2 + a,$$

where Y' is the predicted value of Y (college GPA), X_1 and X_2 are the values of the predictor variables (ACT score and high school GPA), b_1 and b_2 are the regression coefficients by which X_1 and X_2 are multiplied to get Y' , and a is the intercept (i.e., value of Y when X_1 and X_2 are both 0). In this particular case, the intercept serves only an arithmetic function as it has no practical interpretability because having a high school GPA of 0 and an ACT score of 0 is meaningless.

Explanation

In social scientific contexts, multiple regression is rarely used to predict unknown values on a criterion variable. In social scientific research, values of the independent and dependent variables are almost always known. In such cases multiple regression is used to test whether and to what extent the independent variables explain the dependent variable. Most often the researcher has theories and hypotheses that specify causal relations among the independent variables and the dependent variable. Multiple regression is a useful tool for testing such hypotheses. For example, an economist is interested in testing a hypothesis about the determinants of workers' salaries. The model being tested could be depicted as follows:

family of origin SES → education → salary,

where SES stands for socioeconomic status.

In this simple model, the economist hypothesizes that the SES of one's family of origin will influence how much formal education one acquires, which in turn will predict one's salary. If the economist collected data on these three variables from a sample of workers, the hypotheses could be tested with a multiple regression model that is comparable to the one presented previously in the college GPA example:

$$Y = b_1X_1 + b_2X_2 + a.$$

In this case, what was Y' is now Y because the value of Y is known. It is useful to deconstruct the components of this equation to show how they can be used to test various aspects of the economist's model.

In the equation above, b_1 and b_2 are the *partial regression coefficients*. They are the weights by which one multiplies the value of X_1 and X_2 when all variables are in the equation. In other words, they represent the expected change in Y , per unit of X when all other variables are accounted for, or held constant. Computationally, the values of b_1 and b_2 can be determined easily by simply knowing the zero-order correlations among all possible pairwise combinations of Y , X_1 , and X_2 , as well as the standard deviations of the three variables:

$$b_1 = \frac{r_{YX_1} - r_{YX_2}r_{X_1X_2}}{1 - r_{X_1X_2}^2} \cdot \frac{s_Y}{s_{X_1}};$$

$$b_2 = \frac{r_{YX_2} - r_{YX_1}r_{X_1X_2}}{1 - r_{X_1X_2}^2} \cdot \frac{s_Y}{s_{X_2}},$$

where r_{YX_1} is the Pearson correlation between Y and X_1 , $r_{X_1X_2}$ is the Pearson correlation between X_1 and X_2 , and so on, and s_Y is the standard deviation of variable Y , s_{X_1} is the standard deviation of X_1 , and so on. The partial regression coefficients are also referred to as

unstandardized regression coefficients because they represent the value by which one would multiply the raw X_1 or X_2 score in order to arrive at Y . In the salary example, these coefficients could look something like this:

$$Y = 745.67X_1 + 104.36X_2 + 11,325.$$

This means that subjects' annual salaries are best described by an equation whereby their family of origin SES is multiplied by 745.67, their years of formal education are multiplied by 104.36, and these products are added to 11,325. Notice how the regression coefficient for SES is much larger than that for years of formal education. Although it might be tempting to assume that family of origin SES is weighted more heavily than years of formal education, this would not necessarily be correct. The magnitude of an unstandardized regression coefficient is strongly influenced by the units of measurement used to assess the independent variable with which it is associated. In this example, assume that SES is measured on a 5-point scale (Levels 1–5) and years of formal education, at least in the sample, runs from 7 to 20. These differing scale ranges have a profound effect on the magnitude of each regression coefficient, rendering them incomparable.

However, it is often the case that researchers want to understand the relative importance of each independent variable for explaining variation in the dependent variable. In other words, which is the more powerful determinant of people's salaries, their education or their family of origin's socioeconomic status? This question can be evaluated by examining the *standardized regression coefficient*, or β . Computationally, β can be determined by the following formulas:

$$\beta_1 = \frac{r_{YX_1} - r_{YX_2}r_{X_1X_2}}{1 - r_{X_1X_2}^2}; \quad \beta_2 = \frac{r_{YX_2} - r_{YX_1}r_{X_1X_2}}{1 - r_{X_1X_2}^2}.$$

The components of these formulas are identical to those for the unstandardized regression coefficients, but they lack multiplication by the ratio of standard deviations of Y and X_1 and X_2 . Incidentally, one can easily convert to b with the following formulas, which illustrate their relationship:

$$b_1 = \beta_1 \frac{s_Y}{s_1} \quad b_2 = \beta_2 \frac{s_Y}{s_2},$$

where s_Y is the standard deviation of variable Y , and so on.

Standardized regression coefficients can be thought of as the weight by which one would multiply a standardized score (or z score) for each independent variable in order to arrive at the z score for the dependent variable. Because z scores essentially equate all variables on the same scale, researchers are inclined to make comparisons about the relative impact of each

independent variable by comparing their associated standardized regression coefficients, sometimes called *beta weights*.

In the economist's hypothesized model of workers' salaries, there are several subhypotheses or research questions that can be evaluated. For example, the model presumes that both family of origin SES and education will exert a causal influence on annual salary. One can get a sense of which variable has a greater impact on salary by comparing their beta weights. However, it is also important to ask whether either of the independent variables is a significant predictor of salary. In effect, these tests ask whether each independent variable explains a statistically significant portion of the variance in the dependent variable, independent of that explained by the other independent variable(s) also in the regression equation. This can be accomplished by dividing the β by its standard error ($SE\beta$). This ratio is distributed as t with degrees of freedom = $n - k - 1$, where n is the sample size and k is the number of independent variables in the regression analysis. Stated more formally,

$$t = \frac{\beta}{SE_{\beta}}.$$

If this ratio is significant, that implies that the particular independent variable uniquely explains a statistically significant portion of the variance in the dependent variable. These t tests of the statistical significance of each independent variable are routinely provided by computer programs that conduct multiple regression analyses. They play an important role in testing hypotheses about the role of each independent variable in explaining the dependent variable.

In addition to concerns about the statistical significance and relative importance of each independent variable for explaining the dependent variable, it is important to understand the collective function of the independent variables for explaining the dependent variable. In this case, the question is whether the independent variables collectively explain a significant portion of the variance in scores on the dependent variable. This question is evaluated with the *multiple correlation coefficient*. Just as a simple bivariate correlation is represented by r , the multiple correlation coefficient is represented by R . In most contexts, data analysts prefer to use R^2 to understand the association between the independent variables and the dependent variable. This is because the squared multiple correlation coefficient can be thought of as the percentage of variance in the dependent variable that is collectively explained by the independent variables. So, an R^2 value of .65 implies that 65% of the variance in the dependent variable is explained by the combination of independent variables. In the case of two independent variables, the formula for the squared multiple

correlation coefficient can be explained as a function of the various pairwise correlations among the independent and dependent variables:

$$R^2 = \frac{r_{YX_1}^2 + r_{YX_2}^2 - 2r_{YX_1}r_{YX_2}r_{X_1X_2}}{1 - r_{X_1X_2}^2}.$$

In cases with more than two independent variables, this formula becomes much more complex, requiring the use of matrix algebra. In such cases, calculation of R^2 is ordinarily left to a computer.

The question of whether the collection of independent variables explains a statistically significant amount of variance in the dependent variable can be approached by testing the multiple correlation coefficient for statistical significance. The test can be carried out by the following formula:

$$F = \frac{R^2(n - k - 1)}{(1 - R^2)k}.$$

This test is distributed as F with $df=k$ in the numerator and $n - k - 1$ in the denominator, where n is the sample size and k is the number of independent variables.

Two important features of the test for significance of the multiple correlation coefficient require discussion. First, notice how the sample size, n , appears in the numerator. This implies that all other things held constant, the larger the sample size, the larger the F ratio will be. That means that the statistical significance of the multiple correlation coefficient is more probable as the sample size increases. Second, the amount of variation in the dependent variable that is not explained by the independent variables, indexed by $1 - R^2$ (this is called error or *residual variance*), is multiplied by the number of independent variables, k . This implies that all other things held equal, the larger the number of independent variables, the larger the denominator, and hence the smaller the F ratio. This illustrates how there is something of a penalty for using a lot of independent variables in a regression analysis. When trying to explain scores on a dependent variable, such as salary, it might be tempting to use a large number of predictors so as to take into account as many possible causal factors as possible. However, as this formula shows, this significance test favors parsimonious models that use only a few key predictor variables.

Methods of Variable Entry

Computer programs used for multiple regression provide several options for the order of entry of each independent variable into the regression equation. The order of entry can make a difference in the results obtained

and therefore becomes an important analytic consideration. In *hierarchical* regression, the data analyst specifies a particular order of entry of the independent variables, usually in separate steps for each. Although there are multiple possible logics by which one would specify a particular order of entry, perhaps the most common is that of causal priority. Ordinarily, one would enter independent variables in order from the most distal to the most proximal causes. In the previous example of the workers' salaries, a hierarchical regression analysis would enter family of origin SES into the equation first, followed by years of formal education. As a general rule, in hierarchical entry, an independent variable entered into the equation later should never be the cause of an independent variable entered into the equation earlier. Naturally, hierarchical regression analysis is facilitated by having a priori theories and hypotheses that specify a particular order of causal priority.

Another method of entry that is based purely on empirical rather than theoretical considerations is *stepwise* entry. In this case, the data analyst specifies the full complement of potential independent variables to the computer program and allows it to enter or not enter these variables into the regression equation, based on the strength of their unique association with the dependent variable. The program keeps entering independent variables up to the point at which addition of any further variables would no longer explain any statistically significant increment of variance in the dependent variable. Stepwise analysis is often used when the researcher has a large collection of independent variables and little theory to explain or guide their ordering or even their role in explaining the dependent variable. Because stepwise regression analysis capitalizes on chance and relies on a post hoc rationale, its use is often discouraged in social scientific contexts.

Assumptions of Multiple Regression

Multiple regression is most appropriately used as a data analytic tool when certain assumptions about the data are met. First, the data should be collected through independent random sampling. Independent means that the data provided by one participant must be entirely unrelated to the data provided by another participant. Cases in which husbands and wives, college roommates, or doctors and their patients both provide data would violate this assumption. Second, multiple regression analysis assumes that there are linear relationships between the independent variables and the dependent variable. When this is not the case, a more complex version of multiple regression known as *non-linear regression* must be employed. A third assumption of multiple regression is that at each possible value of

each independent variable, the dependent variable must be normally distributed. However, multiple regression is reasonably robust in the case of modest violations of this assumption. Finally, for each possible value of each independent variable, the variance of the residuals or errors in predicting Y (i.e., $Y' - Y$) must be consistent. This is known as the homoscedasticity assumption. Returning to the workers' salaries example, it would be important that at each level of family-of-origin SES (Levels 1–5), the degree of error in predicting workers' salaries was comparable. If the salary predicted by the regression equation was within $\pm \$5,000$ for everyone at Level 1 SES, but it was within $\pm \$36,000$ for everyone at Level 3 SES, the homoscedasticity assumption would be violated because there is far greater variability in residuals at the higher compared with lower SES levels. When this happens, the validity of significance tests in multiple regression becomes compromised.

MULTIPLE TREATMENT INTERFERENCE

Multiple treatment interference is a threat to the internal validity of a group design. A problem occurs when participants in one group have received all or some of a treatment in addition to the one assigned as part of an experimental or quasi-experimental design. In these

situations, the researcher cannot determine what, if any, influence on the outcome is associated with the nominal treatment and what variance is associated with some other treatment or condition. In terms of independent and dependent variable designations, multiple treatment interference occurs when participants were meant to be assigned to one level of the independent variable (e.g., a certain group with a researcher assigned condition) but were functionally at a different level of the variable (e.g., they received some of the treatment meant for a comparison group). Consequently, valid conclusions about cause and effect are difficult to make.

There are several situations that can result in multiple treatment interference, and they can occur in either experimental designs (which have random assignment of participants to groups or levels of the independent variable) or quasi-experimental designs (which do not have random assignment to groups). One situation might find one or more participants in one group receiving accidentally, in addition to their designated treatment, the treatment meant for a second group. This can happen administratively in medicine studies, for example, if subjects receive both the drug they are meant to receive and, accidentally, are also given the drug meant for a comparison group. If benefits are found in both groups or in the group meant to receive a placebo (for example), it is unclear whether effects are due to the experimental drug, the placebo, or a combination of the two. The ability to isolate the effects of the experimental drug or (more generally in research design) the independent variable on the outcome variable is the strength of a good research design, and consequently, strong research designs attempt to avoid the threat of multiple treatment interference. A second situation involving multiple treatment interference is more common, especially in the social sciences. Imagine an educational researcher interested in the effects of a new method of reading instruction. The researcher has arranged for one elementary teacher in a school building to use the experimental approach and another elementary teacher to use the traditional method. As is typically the case in educational research, random assignment to the two classrooms is not possible. Scores on a reading test are collected from both classrooms as part of a pre-post test design. The design looks like this:

Experimental Group:

Pretest → 12 weeks of instruction → Posttest

Comparison Group:

Pretest → 12 weeks of instruction → Posttest

If the study were conducted as planned, comparisons of posttest means for the two groups, perhaps after controlling for initial differences found at the time of the pretest, would provide fairly valid evidence of the comparative effectiveness of the new method. The conclusion is predicated, though, on the assumption that students in the traditional classroom were not exposed to the experimental method. Often, in the real world, it is difficult to keep participants in the control or comparison group free from the “contamination” of the experimental treatment. In the case of this example, the teacher in the comparison group may have used some of the techniques or strategies included in the experimental approach. He may have done this inadvertently, or intentionally, deciding that ethically he should use the best methods he knows. Contamination might also have been caused by the students’ partial exposure to the new instructional approach in some circumstance outside of the classroom—a family member in the other classroom may have brought homework home and shared it with a student, for example.

Both of these examples describe instances of multiple treatment interference. Because of participants’ exposure to more than only the intended treatment, it becomes difficult for researchers to establish relationships between well-defined variables. When a researcher believes that multiple treatments might be effective or wishes to investigate the effect of multiple treatments, however, a design can be applied that controls the combinations of treatments and investigates the consequences of multiple treatments. Drug studies sometimes are interested in identifying the benefits or disadvantages of various interactions or combinations of treatments, for example. A study interested in exploring the effects of multiple treatments might look like this (assuming random assignment):

Group 1: Treatment 1 → Measure outcome

Group 2: Treatment 2 → Measure outcome

Group 3: Treatment 1, followed by Treatment 2 → Measure outcome

Group 4: Treatment 2, followed by Treatment 1 → Measure outcome

A statistical comparison of the four groups’ outcome means would identify the optimum treatment—Treatment 1, Treatment 2, or a particular sequence of both treatments.

MULTIPLICITY PROBLEM

Typically, a research project involves testing multiple research hypotheses. These research hypotheses could be evaluated using, for example, comparisons of means, bivariate correlations, or regressions. In fact, most studies consist of a mixture of several different types of test statistics. An important consideration when conducting multiple tests of significance is how to deal with the increased likelihood (relative to conducting a single test of significance) of falsely declaring one (or more) hypothesis(es) statistically significant (i.e., a Type I error). This is termed the *multiplicity* problem. This multiplicity problem is especially relevant to the topic of research design because the issues associated with the multiplicity problem relate directly to designing studies (i.e., number and nature of variables to include) and deriving a data analysis strategy (e.g., number of relationships to investigate) for the study. This entry introduces the multiplicity problem, in addition to discussing some of the strategies that have been proposed for dealing with the problem.

Introduction to the Multiplicity Problem

To help clarify the multiplicity problem, imagine a soldier who needed to cross fields containing land mines in order to obtain supplies. It is clear that the more fields the individual crosses, the greater the probability that they would activate a land mine; likewise, researchers conducting many tests of significance have an increased chance of erroneously finding tests that are statistically significant.

For instance, imagine that a researcher is interested in determining whether overall course ratings differ for lecture, seminar, or computer-mediated instruction

formats. In this type of experiment, researchers are often interested in whether significant differences exist between any pair of formats. For example, do the ratings of students in lecture-format classes differ from the ratings of students in seminar-format classes? The multiplicity problem in this situation is that in order to compare each format in a pairwise manner, three tests of statistical significance need to be conducted (i.e., comparing the means of lecture vs. seminar, lecture vs. computer-mediated, and seminar vs. computer-mediated instruction). There are numerous ways of addressing the multiplicity problem (i.e., dealing with the increased likelihood of falsely declaring tests statistically significant). It is hoped that this entry will help clarify many of the issues surrounding the multiplicity issue.

Common Multiple Testing Situations

There are many different settings in which researchers conduct null hypothesis significance testing (NHST). The following are just a few of the more common settings where multiplicity issues arise:

- a) conducting pairwise and/or complex contrasts in a linear model with categorical variables;
- b) conducting multiple main effect and interaction tests in a factorial analysis of variance (ANOVA) or multiple regression setting;
- c) analyzing multiple simple effect, interaction contrast, or simple slope tests when analyzing interactions in linear models;
- d) analyzing multiple univariate ANOVAs following a significant multivariate analysis of variance;
- e) analyzing multiple correlation coefficients;
- f) assessing the significance of multiple factor loadings or factor correlations in factor analysis;
- g) analyzing multiple dependent variables separately in linear models;
- h) evaluating multiple parameters simultaneously in a structural equation model; and
- i) analyzing multiple brain voxels for stimulation in functional MRI research.

Further, as stated previously, most studies involve a mixture of many different types of test statistics.

An important factor in understanding the multiplicity problem is understanding the different ways in which a researcher can “group” their tests of significance. For example, suppose in the study looking at whether student ratings differ across instruction

formats that there was also another independent variable, the sex of the instructor. There would now be two “main effect” variables (instruction format and sex of the instructor) and potentially a hypothesis regarding the interaction between instruction format and sex of the instructor. On one hand, the researcher might want to “group” the hypotheses tested under each of the main effect (e.g., pairwise comparisons) and interaction (e.g., simple effect tests) hypotheses into separate “families,” where a family is defined as a group of related hypotheses that are considered simultaneously in the decision process. Therefore, control of the Type I error rate might be imposed separately for each family, or in other words, the Type I error rate for each of the main effect and interaction “families” is maintained at α (the maximum permissible rate of Type I errors for a specific test). On the other hand, the researcher may prefer to treat the entire set of tests for all main effects and interactions as one family, depending on the nature of the analyses and the way in which inferences regarding the results will be made. The central point here is that when researchers conduct multiple tests of significance, they must make important decisions about *how* their tests are related, and these decisions will directly affect the power and Type I error rates for both the individual tests and for the group of tests conducted in the study.

Multiplicity Control

Researchers testing multiple hypotheses, each with a specified Type I error probability α , risk an increase in the overall probability of committing a Type I error as the number of tests increases (i.e., the multiplicity problem). In some cases, the need for Type I error control is more apparent. For example, if the goal of the researcher comparing the three classroom instruction formats was to identify the most effective instruction method that would then be adopted in schools, it would be important to ensure that a method was not selected as superior by chance (i.e., a Type I error). However, if the goal of the research was simply to identify the best classroom formats for future research (with no immediate practical implications), the risks associated with Type I errors would be reduced, whereas the risk of not identifying a possibly superior method (i.e., a Type II error) would be increased (because missing out on a potentially superior method might mean dismissing that method from further study). When many hypotheses are being tested, researchers must specify not only the level of significance but also the unit of analysis (i.e., family) over which Type I error control will be applied. For example, the researcher comparing the lecture, seminar,

and computer-mediated instruction formats must determine how Type I error control will be imposed over the three pairwise tests. On one hand, if the probability of committing a Type I error is set at α for each comparison, then the probability that at least one Type I error is committed over all three pairwise comparisons can be much higher than α . On the other hand, if the probability of committing a Type I error is set at α for all tests conducted, then the probability of committing a Type I error for each of the unique comparisons can be much lower than α . The conclusions of a study can be greatly affected by the unit of analysis over which Type I error control is imposed.

Units of Analysis

Several different units of analysis (i.e., error rates) have been proposed in the multiplicity literature. The majority of the discussion has focused on the per-test and familywise error rates, although other error rates, such as the false discovery rate, have been proposed.

Per-Test Error Rate

Controlling the per-test error rate (α_{PT}) involves simply setting the α level for each test (α_T) equal to the global α level.

Familywise Error Rate

The familywise error rate (α_{FW}) is defined as the probability of falsely rejecting one or more hypotheses in a family of hypotheses. Although many multiplicity control procedures purport to control α_{FW} , procedures are said to provide *strong* α_{FW} control if α_{FW} is maintained at approximately α under the complete null (e.g., all population means are equal) *and* under partial nulls (e.g., multiple subsets of the population means are equal, although the complete null is false). Procedures that control α_{FW} for the complete null, but not for partial nulls, provide *weak* α_{FW} control.

False Discovery Rate

False discovery rate (α_{FDR}) control represents a compromise between strict α_{FW} control and liberal α_{PT} control. α_{FDR} is defined as the expected ratio, $E(Q)$, of the number of erroneous rejections (V) to the total number of rejections (R , where $R = V + S$, and S represents the number of true rejections). Therefore, $E(Q) = E(V/(V + S)) = E(V/R)$. If all null hypotheses are true, $\alpha_{FDR} = \alpha_{FW}$ (since $S = 0$ and therefore $\alpha_{FDR} = \alpha_{FW} = 1$ if there are any rejections). However, if some null hypotheses are false, $\alpha_{FDR} \leq \alpha_{FW}$, resulting in weak control of α_{FW} . As a result, any procedure that controls

α_{FW} also controls α_{FDR} , but procedures that control α_{FDR} can be much more powerful than α_{FW} controlling procedures, especially when a large number of tests is performed, and do not entirely dismiss the multiplicity issue (as with α_{PT} control).

Multiple Testing Procedures

This section introduces some of the multiple testing procedures that are available for controlling α_{FW} and α_{FDR} . Recall that no procedure is necessary for controlling α_{PT} as the α level for each test is equal to the global α level and therefore no adjustment for multiplicity is required. It is important to note that this is only a small subset of the procedures that are available, and for the procedures that are presented, detailed descriptions are not provided.

Familywise Error Controlling Procedures

Bonferroni

This simple to use procedure sets $\alpha_T = \alpha/T$, where T represents the number of tests being performed. The important assumption of the Bonferroni procedure is that the tests being conducted are independent; when this assumption is violated (and it commonly is), the procedure will be conservative.

Holm

Sture Holm proposed a sequential modification of the original Bonferroni procedure that can be substantially more powerful than the Bonferroni procedure, while still maintaining strong α_{FW} control.

False Discovery Rate Controlling Procedures

FDR-BH

Yoav Benjamini and Yosef Hochberg proposed the original procedure for controlling the α_{FDR} , which is a sequential modified Bonferroni procedure.

FDR-BY

Yoav Benjamini and Daniel Yekutieli proposed a modified α_{FDR} controlling procedure that would maintain $\alpha_{FDR} = \alpha$ under any dependency structure among the tests.

Which Unit of Analysis Is Most Appropriate?

Controlling α_{FW} has been recommended when some effects are likely to be nonsignificant, when the researcher is prepared to perform many tests of

significance in order to find a significant result, when the researcher's analysis is exploratory yet the researcher still wants to be confident that a significant result is real, and when replication of the experiment is unlikely. The main advantage of α_{FW} control is that the probability of making a Type I error does not increase with the number of comparisons conducted in the study. One of the main disadvantages of procedures that control α_{FW} is that α_T decreases, often substantially, as the number of tests increases. Therefore, procedures that control α_{FW} have reduced power for detecting treatment effects when there are many comparisons, increasing the potential for inconsistent results between experiments.

Although some researchers recommend exclusive use of α_{FDR} control, most multiplicity researchers would recommend that α_{FDR} control be reserved for exploratory research, nonsimultaneous inference (e.g., separate inferences regarding each hypothesis), and very large family sizes (e.g., investigating potential activation of thousands of brain voxels in functional MRI).

The primary disadvantage of α_{PT} control is that the probability of making at least one Type I error increases as the number of tests increases. The actual increase in the probability depends, among other factors, on the degree of correlation among the tests. For independent tests, the probability of a Type I error with T tests is $1 - (1 - \alpha)^T$, whereas for nonindependent tests (e.g., all pairwise comparisons, multiple path coefficients in structural equation modeling), the probability of a Type I error is less than $1 - (1 - \alpha)^T$.

Although many researchers, journals, and associative bodies still recommend or require that some form of multiplicity control is utilized when conducting multiple tests of statistical significance, the movement to abandon these practices (and instead adopt α_{PT} control) has been gaining traction. Recommendations for controlling α_{PT} (i.e., ignoring the multiplicity problem) revolve around a few simple, but convincing, arguments. First, it can be argued that the natural unit of analysis is the individual test (not any artificially construed *family*). In other words, each test should be considered independent of how many other tests are being conducted as part of that specific analysis, that particular study or, for that matter, how many tests the researcher might conduct over their career. Second, in many disciplines, it is difficult to imagine a traditional hypothesis, to enough decimal places, being true (e.g., $H_0: \mu_1 = \mu_2$; $H_0: \rho = 0$); if there are no true null hypotheses, then there is no such thing as a Type I error, and thus no need for multiplicity control. Third, is the issue of (in)consistency; when multiplicity control is invoked, different conclusions can be found regarding the same

hypothesis, even if the test statistics are identical, because α_T depends on the number of tests being conducted. Fourth, multiplicity control was designed to minimize the number of false positives that exist in the research literature; however, isn't that the job of replication? As replications gain respect and popularity, we can count on them to weed out null effects from the literature. Lastly is the recent shift in attention from traditional NHST to the *new statistics*, including effect sizes, confidence intervals, and meta-analysis. Multiplicity (or Type I error) control is not an issue when the focus is on effect size magnitude and precision, rather than dichotomous decisions regarding the null hypothesis.

Final Thoughts

To summarize, several options are available when multiple tests of significance are performed, and the best form of multiplicity control depends on the nature and goals of the research. Although familywise or false discovery rate control is currently recommended by most, in the quickly changing research environment, where effect sizes, confidence intervals, replication, and meta-analysis now dominate over NHST, support is gaining for ignoring the multiplicity problem all together.

MULTISITE RESEARCH STUDIES

Multisite research is a design or approach for examining an intervention in two or more geographically distinct sites. The method is well suited for prevention and evaluation studies, where a researcher is interested in the effects of a policy or program intervention that spans across multiple contexts. In some cases, the intervention is designed to be implemented in the same way at each site. In others, the intervention is intended to achieve similar outcomes across sites, but its implementation varies to fit the local context. In these scenarios, a researcher may be interested in comparing the relative effectiveness of variations in the intervention on similar outcome measures. This entry discusses the advantages to multisite research studies, as well as some challenges to conducting these studies.

Advantages to Multisite Research Studies

Multisite research designs offer several significant advantages. First, including multiple sites can allow for a larger sample size than would be possible at a single site. A larger sample size can increase the statistical power of analyses to determine whether the intervention produces the desired outcomes.

Second, including multiple sites can allow for a more diverse sample. It may not be possible to recruit a sample that contains characteristics that are representative of the target population at a single site. By increasing the diversity of sites and participants involved, a multisite research study can increase the generalizability of findings across participant and site characteristics, such as the location of the site or participant demographics.

Similarly, multiple sites may be needed to obtain adequate sample sizes of particular subgroups of interest from which to form subgroup analyses. These analyses are used to determine whether the effects of the intervention differ across subgroups in the population. For example, through subgroup analyses, a researcher may observe an interaction between the intervention and certain participant characteristics, such as ethnicity or socioeconomic status. Therefore, these analyses are important in determining for whom in the target population the findings can be generalized to.

Challenges to Conducting Multisite Research

Accompanying the considerable advantages to conducting multisite research studies are key challenges

that the researcher should consider. The first challenge for a multisite researcher is in selecting sites for participation. The researcher must balance creating a diverse sample that is representative of the target population while maintaining enough similarity between sites to estimate overall intervention effects. If sites are too distinct from one another, it may not be sensible to pool data for analysis. Therefore, when selecting sites, the researcher should determine which characteristics need to be represented in the sample, such as particular participant demographics, while also considering which factors should remain the same across sites, such as the site's capacity to conduct the intervention.

Second, a challenge concerns maintaining consistency in the implementation of the research. The level of standardization needed in research procedures can depend on the purpose of the multisite study. Studies that are more exploratory in nature, such as those that focus on describing an intervention, may not need to stringently follow rigorous procedures to ensure that methods of data collection and measurement are the same across sites. In contrast, studies that seek to provide evidence of intervention effectiveness must increase the standardization of study design and measures to allow for data to be pooled for analysis. These intervention studies, common in the medical field, must have a standard set of research questions in addition to developing shared definitions of measures, standardizing data collection protocols, and developing methods of quality control to monitor the level of consistency in research procedures across sites. Methods of quality control can include training site data collectors or traveling to each site to oversee components of data collection. Attention to standardizing the study design is especially important when the sampled sites maintain distinct characteristics or geographical locations. By striving for consistency in study implementation, the researcher decreases the likelihood that differences in outcomes across sites are due to issues of measurement or study procedures.

Likewise, a third challenge to multisite research arises in studies where the intervention is intended to be the same across sites. In these cases, the researcher should monitor the consistency of sites' implementation of the intervention or incorporate implementation data into the analysis. Differences in how the intervention is implemented may be related to particular site-level characteristics. Understanding variations in intervention implementation can help to explain any observed differences in outcomes across sites.

Last, although increased diversity is a benefit of multisite designs, it can also complicate data analysis. When pooling data, a multisite researcher should

utilize data analysis strategies that account for differences across sites. For example, hierarchical linear modeling is one technique that controls for the random effects of site-level characteristics rather than assuming a fixed effect of sites on the intervention outcome. Not accounting for differences across sites during data analysis can lead to an overestimation of intervention effects and, as a result, inaccurate study conclusions. When examining individual-level differences, the inclusion of moderators can be used to detect differing effects of the intervention between subgroups within the sample.

If challenges to multisite research are addressed in study design and implementation, multisite research studies offer an opportunity to not only examine the impact of a policy or program across a diverse sample but also to understand how effects may vary across contextual and participant features. The increased generalizability that these studies provide can enhance the validity and usability of evidence to inform policy and practice decisions.

MULTITRAIT–MULTIMETHOD MATRIX

The multitrait–multimethod (MTMM) matrix contains the correlations between variables when each variable represents a trait–method unit, that is, the measurement of a trait (e.g., extroversion, neuroticism) by a specific method (e.g., self-report, peer report). In order to obtain the matrix, each trait has to be measured by the same set of methods. This makes it possible to arrange the correlations in such a way that the correlations between different traits measured by the same method can be separated from the correlations between different traits measured by different methods. The MTMM matrix was recommended by Donald T.

Campbell and Donald W. Fiske as a means of measuring the convergent and discriminant validity. This entry discusses the structure, evaluation, and analysis approaches of the MTMM matrix.

Structure of the MTMM Matrix

Table 1 shows a prototypical MTMM matrix for three traits measured by three methods. An MTMM matrix consists of two major parts: monomethod blocks and heteromethod blocks.

Monomethod Blocks

The monomethod blocks contain the correlations between variables that belong to the same method. In Table 1 there are three monomethod blocks, one for each method. Each monomethod block consists of two parts. The first part (reliability diagonals) contains the reliabilities of the measures. The second part (the heterotrait–monomethod triangles) include the correlations between different traits that are measured by the same methods. The reliabilities can be considered as monotrait–monomethod correlations.

Heteromethod Blocks

The heteromethod blocks comprise the correlations between traits that were measured by different methods. Table 1 contains three heteromethod blocks, one for each combination of the three methods. A heteromethod block consists of two parts. The validity diagonal (monotrait–heteromethod correlations) contains the correlations of the same traits measured by

Table 1 Multitrait–Multimethod Matrix for Three Traits Measured by Three Methods

		Method 1			Method 2			Method 3		
Traits		Trait 1	Trait 2	Trait 3	Trait 1	Trait 2	Trait 3	Trait 1	Trait 2	Trait 3
Method 1	Trait 1	(.90)								
	Trait 2	.10	(.90)							
	Trait 3	.10	.10	(.90)						
Method 2	Trait 1	.50	.12	.12	(.80)					
	Trait 2	.14	.50	.12	.20	(.80)				
	Trait 3	.14	.14	.50	.20	.20	(.80)			
Method 3	Trait 1	.50	.05	.05	.40	.03	.03	(.85)		
	Trait 2	.04	.50	.05	.02	.40	.03	.30	(.85)	
	Trait 3	.04	.04	.50	.02	.02	.40	.30	.30	(.85)

Notes: The correlations are artificial. Reliabilities are in parentheses. Heterotrait–monomethod correlations are in the gray subdiagonals. Heterotrait–heteromethod correlations are enclosed by a broken line. Monotrait–heteromethod correlations in the convergent validity diagonals are in bold type.

different methods. The heterotrait–heteromethod triangles cover the correlations of different traits measured by different methods.

Criteria for Evaluating the MTMM Matrix

Campbell and Fiske described four properties an MTMM matrix should show when convergent and discriminant validity is present:

1. The correlations in the validity diagonals (monotrait–heteromethod correlations) should be significantly different from 0 and they should be large. These correlations indicate convergent validity.
2. The heterotrait–heteromethod correlations should be smaller than the monotrait–heteromethod correlations (discriminant validity).
3. The heterotrait–monomethod correlations should be smaller than the monotrait–heteromethod correlations (discriminant validity).
4. The same pattern of trait intercorrelations should be shown in all heterotrait triangles in the monotrait as well as in the heteromethod blocks (discriminant validity).

Limitations of These Rules

These four requirements have been developed by Campbell and Fiske because they are easy-to-apply rules for evaluating an MTMM matrix with respect to its convergent and discriminant validity. They are, however, restricted in several ways. The application of these criteria is difficult if the different measures differ in their reliabilities. In this case the correlations, which are correlations of observed variables, can be distorted by measurement error in different ways, and differences between correlations could only be due to differences in reliabilities. Moreover, there is no statistical test of whether these criteria are fulfilled in a specific application. Finally, the MTMM matrix is not explained by a statistical model allowing the separation of different sources of variance that are due to trait, method, and error influences. Modern psychometric approaches complete these criteria and circumvent some of these problems.

Modern Psychometric Approaches for Analyzing the MTMM Matrix

Many statistical approaches, such as analysis of variance and generalizability theory, multilevel modeling, and item response theory, have been applied to analyze MTMM data sets. Among all methods, direct

product models and models of confirmatory factor analyses have been the most often applied and influential approaches.

Direct Product Models

The basic idea of direct product models is that each correlation of an MTMM matrix is assumed to be a product of two correlations: a correlation between traits and a correlation between methods. For each combination of traits, there is a correlation indicating discriminant validity, and for each combination of methods, there is a correlation indicating the degree of convergent validity. For example, the heterotrait–heteromethod correlation $Cor(T_1M_1, T_2M_2)$ between a trait T_1 (measured by a method M_1) and a trait T_2 (measured by a method M_2) is the product of the correlations $Cor(T_1, T_2)$ and $Cor(M_1, M_2)$:

$$Cor(T_1M_1, T_2M_2) = Cor(T_1, T_2) \times Cor(M_1, M_2).$$

If the two traits are measured by the same method (e.g., M_1), the method intercorrelation is 1 ($Cor[M_1, M_1] = 1$), and the observed correlation equals the correlation between the two traits:

$$Cor(T_1M_1, T_2M_1) = Cor(T_1, T_2).$$

If the two traits, however, are measured by different methods, the correlation of the traits is attenuated by the correlation of the methods. Hence, the smaller the convergent validity, the smaller are the expected correlations between the traits.

The four properties of the MTMM matrix proposed by Campbell and Fiske can be evaluated by the correlations of the direct product model:

1. The correlations between two methods (convergent validity) should be large.
2. The second property is always fulfilled when the correlation between two traits is smaller than 1, because the direct product model always implies, in this case,

$$\begin{aligned} &Cor(T_1, T_1) \times Cor(M_1, M_2) > \\ &Cor(T_1, T_2) \times Cor(M_1, M_2). \end{aligned}$$

3. The third property is satisfied when the correlations between methods are larger than the correlations between traits because $Cor(T_1, T_1) = Cor(M_1, M_1) = 1$, and in this case,

$$\begin{aligned} &Cor(T_1, T_1) \times Cor(M_1, M_2) > \\ &Cor(T_1, T_2) \times Cor(M_1, M_1). \end{aligned}$$

4. The fourth requirement is always fulfilled if the direct product model holds because the trait intercorrelations in all heteromethod blocks are weighted by the same method correlation. This makes sure that the ratio of two trait correlations is the same for all mono-method and heteromethod blocks.

The direct product model has been extended by Michael Browne to the *composite direct product model* by the consideration of measurement error. Direct product models are reasonable models for analyzing MTMM matrices. They are, however, also limited in at least two respects. First, they do not allow the decomposition of variance in components due to trait, method, and error influences. Second, they presuppose that the correlations between the traits do not differ between the different monomethod blocks.

Models of Confirmatory Factor Analysis

During recent years many different MTMM models of confirmatory factor analysis (CFA) have been developed. Whereas the first models were developed for decomposing the classical MTMM matrix that is characterized by a single indicator for each trait–method unit, more recently formulated models consider multiple indicators for each trait–method unit.

Single Indicator Models

Single indicator models of CFA decompose the observed variables into different components representing trait, method, and error influences. Moreover, they differ in the assumptions they make concerning the homogeneity of method and trait effects, as well as admissible correlations between trait and method factors. Keith Widaman, for example, describes a taxonomy of 16 MTMM-CFA models by combining four different types of trait structures (no trait factor, general trait factor, several orthogonal trait factors, several oblique trait factors) with four types of method structures (no method factor, general method factor, several orthogonal method factors, several oblique method factors).

In the most general single-indicator MTMM model, an observed variable Y_{jk} , indicating a trait i measured by a method k , is decomposed into a trait factor T_i , a method factor M_k , and a residual variable E_{jk} :

$$Y_{jk} = \alpha_{jk} + \lambda_{Tjk}T_i + \lambda_{Mjk}M_k + E_{jk},$$

where α_{jk} is an intercept, λ_{Tjk} is a trait loading, and λ_{Mjk} is a method loading. The trait factors are allowed to be correlated. The correlations indicate the degree of

Figure 1 Correlated-Trait–Correlated-Method Model

discriminant validity. Also, the method factors are allowed to be correlated. These method intercorrelations show whether method effects generalize across methods. This model is called a *correlated-trait–correlated-method* (CTCM) model and is depicted in Figure 1.

The model has several advantages. It allows researchers to decompose the variance of an observed variable into the variance due to trait, method, and error influences. Convergent validity is given when the variances due to the method factors are small. In the ideal case of perfect convergent validity, the variances of all method factors would be 0, meaning that there are no method factors in the model (so-called *correlated trait model*). Perfect discriminant validity could be present if the trait factors are uncorrelated. Method factors could be correlated, indicating that the different methods can be related in a different way. However, aside from these advantages, this model is affected by serious statistical and conceptual problems. One statistical problem is that the model is not generally identified, which means that there are data constellations in which it is not possible to estimate the parameters of the model. For example, if all factor loadings do not differ from each other, the model is not identified. Moreover, applications of this model often show nonadmissible parameter estimates (e.g., negative variances of method factors), and the estimation process often does not converge. From a more conceptual point of view, the model has been criticized because it allows correlations between method factors. These correlations make the interpretation of the correlations between trait factors more difficult. If, for example, all trait factors are uncorrelated, this would indicate perfect discriminant validity. However, if all method factors are correlated, it is difficult to interpret the uncorrelatedness of the trait factors as perfect discriminant validity because the

method factor correlations represent a portion of variance shared by all variables that might be due to a general trait effect.

The major problems of the CTCM model are caused by the correlated method factors. According to Michael Eid, Tanja Lischetzke, and Fridtjof Nussbeck, the problems of the CTCM model can be circumvented by dropping the correlations between the method factors or by dropping one method factor. A CTCM model without correlations between method factors is called a *correlated-trait-uncorrelated-method* (CTUM) model. This model is a special case of the model depicted in Figure 1 but with uncorrelated method factors. This model is reasonable if correlations between method factors are not expected. According to Eid and colleagues, this is the case when interchangeable methods are considered. Interchangeable methods are methods that are randomly chosen from a set of methods. If one considers different raters as different methods, an example of interchangeable raters (methods) is randomly selected students rating their teacher. If one randomly selects three students for each teacher and if one assigns these three students randomly to three rater groups, the three method factors would represent the deviation of individual raters from the expected (mean) rating of the teacher (the trait scores). Because the three raters are interchangeable, correlations between the method factors would not be expected. Hence, applying the CTUM model in the case of interchangeable raters would circumvent the problems of the CTCM model.

The situation, however, is quite different in the case of structurally different methods. An example of structurally different methods is a self-rating, a rating by the parents, and a rating by the teacher. In this case, the three raters are not interchangeable but are structurally different. In this case, the CTUM model is not reasonable as it may not adequately represent the fact that teachers and parents can share a common view that is not shared with the student (correlations of method effects). In this case, dropping one method factor solves the problem of the CTCM model in many cases. This model with one method factor less than the number of methods considered is called the *correlated-trait-correlated-(method – 1) model* (CTC[M – 1]). This model is a special case of the model depicted in Figure 1 but with one method factor less. If the first method in Figure 1 is the self-report, the second method is the teacher report, and the third method is the parent report, dropping the first method factor would imply that the three trait factors equal the true-score variables of the self-reports. The self-report method would play the role of the reference method that has to be chosen in this model. Hence, in the

CTC(M – 1) model, the trait factor is completely confounded with the reference method. The method factors have a clear meaning. They indicate the deviation of the true (error-free) other reports from the value predicted by the self-report. A method effect is that (error-free) part of a nonreference method that cannot be predicted by the reference method. The correlations between the two method factors would then indicate that the two other raters (teachers and parents) share a common view of the child that is not shared by the child herself or himself. This model allows contrasting methods, but it does not contain common “method-free” trait factors. It is doubtful that such a common trait factor has a reasonable meaning in the case of structurally different methods.

All single indicator models presented so far assume that the method effects belonging to one method are unidimensional as there is one common method factor for each method. This assumption could be too strong as method effects could be trait specific. Trait-specific method effects are part of the residual in the models presented so far. That means that reliability will be underestimated because a part of the residual is due to method effects and not due to measurement error. Moreover, the models may not fit the data in the case of trait-specific method effects. If the assumption of unidimensional method factors for a method is too strong, the method factors can be dropped and replaced by correlated residuals. For example, if one replaces the method factors in the CTUM model by correlations of residuals belonging to the same methods, one obtains the *correlated-trait-correlated-uniqueness* (CTCU) model. However, in this model the reliabilities are underestimated because method effects are now part of the residuals. Moreover, the CTUM model does not allow correlations between residuals of different methods. This might be necessary in the case of structurally different methods. Problems that are caused by trait-specific method effects can be appropriately handled in multiple indicator models.

Multiple Indicator Models

In multiple indicator models, there are several indicators for one trait–method unit. In the less restrictive model, there is one factor for all indicators belonging to the same trait–method unit. The correlations between these factors constitute a latent MTMM matrix. The correlation coefficients of this latent MTMM matrix are not distorted by measurement error and allow a more appropriate application of the Campbell and Fiske criteria for evaluating the MTMM matrix. Multiple indicator models allow the definition of trait-specific method factors and, therefore, the

separation of measurement error and method-specific influences in a more appropriate way. Eid and colleagues have shown how different models of CFA can be defined for different types of methods. In the case of interchangeable methods, a multilevel CFA model can be applied that allows the specification of trait-specific method effects. In contrast to the extension of the CTCU model to multiple indicators, the multilevel approach has the advantage that the number of methods (e.g., raters) can differ between targets. In the case of structurally different raters, an extension of the CTC(M - 1) model to multiple indicators can be applied. This model allows a researcher to test specific hypotheses about the generalizability of method effects across traits and methods. In the case of a combination of structurally different and interchangeable methods, a multilevel CTC(M - 1) model would be appropriate.

MULTIVALUED TREATMENT EFFECTS

The term *multivalued treatment effects* broadly refers to a collection of population parameters that capture the impact of a given treatment assigned to each observational unit, when this treatment status takes multiple values. In general, treatment levels may be finite or infinite as well as ordinal or cardinal, leading to a large collection of possible treatment effects to be studied in applications. When the treatment effect of interest is the mean outcome for each treatment level, the resulting population parameter is typically called the *dose-response function* in the statistical literature, regardless of whether the treatment levels are finite or infinite. The analysis of multivalued treatment effects has several distinct features when compared with the analysis of binary treatment effects, including the following: (a) A comparison or control group is not always clearly defined, (b) new parameters of interest arise capturing distinct phenomena such as nonlinearities or tipping points, (c) in most cases correct statistical inferences require the joint estimation of all treatment effects (as opposed to the estimation of each treatment effect at a time), and (d) efficiency gains in statistical inferences may be obtained by exploiting known restrictions among the multivalued treatment effects. This entry discusses the treatment effect model and statistical inference procedures for multivalued treatment effects.

Treatment Effect Model and Population Parameters

A general statistical treatment effect model with multivalued treatment assignments is easily described in the context of the classical potential outcomes model. This model assumes that each unit i in a population has an underlying collection of potential outcome random variables $\{Y_i = Y_i(t) : t \in \mathcal{T}\}$, where $\mathcal{T}$ denotes the collection of possible treatment assignments. The random variables $Y_i(t)$ are usually called *potential outcomes* because they represent the random outcome that unit i would have under treatment regime $t \in \mathcal{T}$. For each unit i and for any two treatment levels, t_1 and t_2 , it is always possible to define the *individual treatment effect* given by $Y_i(t_1) - Y_i(t_2)$, which may or may not be

a degenerate random variable. However, because units are not observed under different treatment regimes simultaneously, such comparisons are not feasible. This idea, known as the *fundamental problem of causal inference*, is formalized in the model by assuming that for each unit i only (Y_i, T_i) observed, where $Y_i = Y_i(T_i)$ and $T_i \in \mathcal{T}$. In words, for each unit i , only the potential outcome for treatment level $T_i = t$ is observed while all other (counterfactual) outcomes are missing. Of course, in most applications, which treatment each unit has taken up is not random and hence further assumptions would be needed to identify the treatment effect of interest.

A binary treatment effect model has $T = \{0, 1\}$, a finite multivalued treatment effect model has $T = \{0, 1, \dots, J\}$ for some positive integer J , and a continuous treatment effect model has $T = [0, 1]$. (Note that the values in T are ordinal, that is, they may be seen just as normalizations of the underlying real treatment levels in a given application.) Many applications focus on a binary treatment effects model and base the analysis on the comparison of two groups, usually called treatment group ($T_i = 1$) and control group ($T_i = 0$). A multivalued treatment may be collapsed into a binary treatment, but this procedure usually would imply some important loss of information in the analysis. Important phenomena such as nonlinearities, differential effects across treatment levels or tipping points, cannot be captured by a binary treatment effect model. A multivalued treatment may be collapsed into a binary treatment, but this procedure usually would imply some important loss of information in the analysis. Important phenomena such as nonlinearities, differential effects across treatment levels or tipping points, cannot be captured by a binary treatment effect model.

Typical examples of multivalued treatment effects are comparisons between some characteristic of the distributions of the potential outcomes. Well-known examples are mean and quantile comparisons, although in many applications other features of these distributions may be of interest. For example, assuming, to simplify the discussion, that the random potential outcomes are equal for all units (this holds, for instance, in the context of random sampling), the mean of the potential outcome under treatment regime $t \in \mathcal{T}$ is given by $\mu(t) = E[Y_i(t)]$. The collection of these means is the so-called dose-response function. Using this estimand, it is possible to construct different multivalued treatment effects of interest, such as pairwise comparisons (e.g., $\mu(t_2) - \mu(t_1)$) or differences in pairwise comparisons, which would capture the idea of nonlinear treatment effects. (In the particular case of binary treatment effects, the only possible pairwise comparison is $\mu(1) - \mu(0)$, which is called the average treatment

effect.) Using the dose-response function, it is also possible to consider other treatment effects that arise as nonlinear transformations of $\mu(t)$, such as ratios, incremental changes, tipping points, or the maximal treatment effect $\mu^* = \max_{t \in \mathcal{T}} \mu(t)$, among many other possibilities. All these multivalued treatment effects are constructed on the basis of the mean of the potential outcomes, but similar estimands may be considered that are based on quantiles, dispersion measures, or other characteristics of the underlying potential outcome distribution. Conducting valid hypothesis testing about these treatment effects requires in most cases the joint estimation of the underlying multivalued treatment effects.

Statistical Inference

There exists a vast theoretical literature proposing and analyzing different statistical inference procedures for multivalued treatment effects. This large literature may be characterized in terms of the key identifying assumption underlying the treatment effect model. This key assumption usually takes the form of a (local) independence or orthogonality condition, such as (a) a conditional independence assumption, which assumes that conditional on a set of observable characteristics, selection into treatment is random, or (b) an instrumental variables assumption, which assumes the existence of variables that induce exogenous changes in the treatment assignment. With the use of an identifying assumption (together with other standard model assumptions), it has been shown in the statistical and econometrics literatures that several parametric, semiparametric, and nonparametric procedures allow for optimal joint inference in the context of multivalued treatments. These results are typically obtained with the use of large sample theory and justify (asymptotically) the use of classical statistical inference procedures involving multiple treatment levels.

MULTIVARIATE ANALYSIS OF VARIANCE (MANOVA)

Multivariate analysis of variance (MANOVA) designs are appropriate when multiple dependent variables are included in the analysis. The dependent variables should represent continuous measures (i.e., interval or ratio data). Dependent variables should be moderately correlated. If there is no correlation at all, MANOVA offers no improvement over an analysis of variance (ANOVA); if the variables are highly correlated, the same variable may be measured more than once. In many MANOVA situations, multiple independent variables, called factors, with multiple levels are included. The independent variables should be categorical (qualitative). Unlike ANOVA procedures that analyze differences across two or more groups on one dependent variable, MANOVA procedures analyze differences across two or more groups on two or more dependent variables. Investigating two or more dependent variables simultaneously is important in various disciplines, ranging from the natural and physical sciences to government and business and to the behavioral and social sciences. Many research questions cannot be answered adequately by an investigation of only one dependent variable because treatments in experimental studies are likely to affect subjects in more than one way. The focus of this entry is on the various types of MANOVA procedures and associated assumptions. The logic of MANOVA and advantages and disadvantages of MANOVA are included.

MANOVA is a special case of the general *linear models*. MANOVA may be represented in a basic linear equation as $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$, where $\mathbf{Y}$ represents a vector of dependent variables, $\mathbf{X}$ represents a matrix of independent variables, $\boldsymbol{\beta}$ represents a vector of weighted regression coefficients, and $\boldsymbol{\varepsilon}$ represents a vector of error terms. Calculations for the multivariate procedures are based on matrix algebra, making hand calculations virtually impossible. For example, the null hypothesis for MANOVA states no difference among the

population mean vectors. The form of the omnibus null hypothesis is written as $H_0 = \mu_1 = \dots = \mu_k$. It is important to remember that the means displayed in the null hypothesis represent mean *vectors* for the population, rather than the population means. The complexity of MANOVA calculations requires the use of statistical software for computing.

Logic of MANOVA

MANOVA procedures evaluate differences in population means on more than one dependent variable across levels of a factor. MANOVA uses a linear combination of the dependent variables to form a new dependent variable that minimizes within-group variance and maximizes between-group differences. The new variable is used in an ANOVA to compare differences among the groups. Use of the newly formed dependent variable in the analysis decreases the Type I error (error of rejecting a true null hypothesis) rate. The linear combination reveals a more complete picture of the characteristic or attribute under study. For example, a social scientist may be interested in the kinds of attitudes that people have toward the environment based on their attitudes about global warming. In such a case, analysis of only one dependent variable (attitude about global warming) is not completely representative of the attitudes that people have toward the environment. Multiple measures, such as attitude toward recycling, willingness to purchase environmentally friendly products, and willingness to conserve water and energy, will give a more holistic view of attitudes toward the environment. In other words, MANOVA analyzes the composite of several variables, rather than analyzing several variables individually.

Advantages of MANOVA Designs

MANOVA procedures control for experiment-wide error rate, whereas multiple univariate procedures increase the Type I error rate, which can lead to rejection of a true null hypothesis. For example, analysis of group differences on three dependent variables would require three univariate tests. If the alpha level is set at .05, there is a 95% chance of not making a Type I error. The following calculations show how the 95% error rate is compounded with three univariate tests: $(.95)(.95)(.95) = .857$ and $1 - .857 = .143$, or 14.3%, which is an unacceptable error rate. In addition, univariate tests do not account for the intercorrelations among variables, thus risking loss of valuable information. Furthermore, MANOVA decreases the Type II error (error of not rejecting a false null hypothesis) rate by detecting group differences that appear only

through the combination of two or more dependent variables.

Disadvantages of MANOVA Designs

MANOVA procedures are more complex than univariate procedures; thus, outcomes may be ambiguous and difficult to interpret. The power of MANOVA may actually reveal statistically significant differences when multiple univariate tests may not show differences. Statistical power is the probability of rejecting the null hypothesis when the null is false. (Power = $1 - \beta$.) The difference in outcomes between ANOVA and MANOVA results from the overlapping of the distributions for each of the groups with the dependent variables in separate analyses. In the MANOVA procedure, the linear combination of dependent variables is used for the analysis. Finally, more assumptions are required for MANOVA than for ANOVA.

Assumptions of MANOVA

The mathematical underpinnings of inferential statistics require that certain statistical assumptions be met. Assumptions for MANOVA designs are (a) multivariate normality, (b) homoscedasticity, (c) linearity, and (d) independence and randomness.

Multivariate Normality

Observations on all dependent variables are multivariately normally distributed for each level within each group and for all linear combinations of the dependent variables. Joint normality in more than two dimensions is difficult to assess; however, tests for univariate normality on each of the variables are recommended. Univariate normality, a prerequisite to multivariate normality, can be assessed graphically and statistically. For example, a quantile–quantile plot resembling a straight line suggests normality. While normality of the univariate tests does not mean that the data are multivariately normal, such tests are useful in evaluating the assumption. MANOVA is insensitive (robust) to moderate departures from normality for large data sets and in situations in which the violations are due to skewed data rather than outliers.

A scatterplot for pairs of variables for each group can reveal data points located far from the pattern produced by the other observations. Mahalanobis distance (distance of each case from the centroid of all the remaining cases) is used to detect multivariate outliers. Significance of Mahalanobis distance is evaluated as a chi-square statistic. A case may be considered an outlier if its Mahalanobis distance is statistically significant at

the $p < .0001$ level. Other graphical techniques, such as box plots and stem-and-leaf plots, may be used to assess univariate normality. Two additional descriptive statistics related to normality are skewness and kurtosis.

Skewness

Skewness refers to the symmetry of the distribution about the mean. Statistical values for skewness range from $\pm\infty$. A perfectly symmetrical distribution will yield a value of zero. In a positively skewed distribution, observations cluster to the left of the mean on the normal distribution curve with the right tail on the curve extended with a small number of cases. The opposite is true for a negatively skewed distribution. Observations cluster to the right of the mean on the normal distribution curve with the left tail on the curve extended with a small number of cases. In general, a skewness value of .7 or .8 is cause for concern and suggests that data transformations may be appropriate.

Kurtosis

Kurtosis refers to the degree of peakedness or flatness of a sample distribution compared with a normal distribution. Kurtosis values may be positive or negative to indicate a high peak or flatness near the mean, respectively. Values within ± 2 standard deviations from the mean or ± 3 standard deviations from the mean are generally considered within the normal range. A normal distribution has zero kurtosis. In addition to graphical techniques, the Shapiro–Wilk W statistic and the Kolmogorov–Smirnov statistic with Lilliefors significance levels are used to assess normality. Statistically significant W or Kolmogorov–Smirnov test results indicate that the distribution is nonnormal.

Homoscedasticity

The variance and covariance matrices for all dependent variables across groups are assumed to be equal. George Box's M statistic tests the null hypothesis of equality of the observed covariance matrices for the dependent variables for each group. A nonsignificant F value with the alpha level set at .001 from Box's M indicates equality of the covariance matrices. MANOVA procedures can tolerate moderate departures from equal variance–covariance matrices when sample sizes are similar.

Linearity

MANOVA procedures are based on linear combinations of the dependent variables; therefore, it is assumed

that linear relationships exist among all pairs of dependent variables and all pairs of covariates across all groups. Consequently, linearity is important for all dependent variable–covariate pairs as well. Linearity may be assessed by examining scatterplots of pairs of dependent variables for each group. The scatterplot displays an elliptical shape to indicate a linear relationship. If both variables are not normally distributed, the assumption of linearity will not hold, and an elliptical shape will not be displayed on the scatterplot. If the linearity assumption is not met, data transformations may be necessary to establish linearity.

Independence and Randomness

Observations are independent of one another. That is, the score for one participant is independent of scores of any other participants for each variable. Randomness means that the sample was randomly selected from the population of interest.

Research Questions for MANOVA Designs

Multivariate analyses cover a broad range of statistical procedures. Common questions for which MANOVA procedures are appropriate are as follows: What are the mean differences between two levels of one independent variable for multiple dependent variables? What are the mean differences between or among multiple levels of one independent variable on multiple dependent variables? What are the effects of multiple independent variables on multiple dependent variables? What are the interactions among independent variables on one dependent variable or on a combination of dependent variables? What are the mean differences between or among groups when repeated measures are used in a MANOVA design? What are the effects of multiple levels of an independent variable on multiple dependent variables when effects of concomitant variables are removed from the analysis? What is the amount of shared variance among a set of variables when variables are grouped around a common theme? What are the relationships among variables that may be useful for predicting group membership? These sample questions provide a general sense of the broad range of questions that may be answered with MANOVA procedures.

Types of MANOVA Designs

Hotelling's T^2

Problems for MANOVA can be structured in different ways. For example, a researcher may wish to

examine the difference between males and females on number of vehicle accidents in the past 5 years and years of driving experience. In this case, the researcher has one dichotomous independent variable (gender) and two dependent variables (number of accidents and years of driving experience). The problem is to determine the difference between the weighted sample mean vectors (centroids) of a multivariate data set. This form of MANOVA is known as the multivariate analog to the Student's t test, and it is referred to as Hotelling's T^2 statistic, named after Harold Hotelling for his work on the multivariate T^2 distribution. Calculation of T^2 is based on the combination of two Student's t ratios and their pooled estimate of correlation. The resulting T^2 is converted into an F statistic and distributed as an F distribution.

One-Way MANOVA

Another variation of the MANOVA procedure is useful for investigating the effects of one multilevel independent variable (factor) on two or more dependent variables. An investigation of differences in mathematics achievement and motivation for students assigned to three different teaching methods is such a situation. For this problem, the researcher has one multilevel factor (teaching method with three levels) and two dependent variables (mathematics test scores and scores on a motivation scale). The objective is to determine the differences among the mean vectors for groups on the dependent variables, as well as differences among groups for the linear combinations of the dependent variables. This form of MANOVA extends Hotelling's T^2 to more than two groups; it is known as the one-way MANOVA, and it can be thought of as the MANOVA analog of the one-way F situation. Results of the MANOVA produce four multivariate test statistics: Pillai's trace, Wilks's lambda (Λ), Hotelling's trace, and Roy's largest root. Usually results will not differ for the first three tests when applied to a two-group study; however, for studies involving more than two groups, tests may yield different results. The Wilks's Λ is the test statistic reported most often in publications. The value of Wilks's Λ ranges from 0 to 1. A small value of Λ indicates statistically significant differences among the groups or treatment effects. Wilks's Λ , the associated F value, hypotheses and error degrees of freedom, and the p value are usually reported. A significant F value is one that is greater than the critical value of F at predetermined degrees of freedom for a preset level of significance. As a general rule, tables for critical values of F and accompanying degrees of freedom are published as appendixes in many research and statistics books.

Factorial MANOVA

Another common variation of multivariate procedures is known as the factorial MANOVA. In this design, the effects of multiple factors on multiple dependent variables are examined. For example, the effects of geographic location and level of education on job satisfaction and attitudes toward work may be investigated via a factorial MANOVA. Geographic location with four levels and level of education with two levels are the factors. Geographic location could be coded as 1 = south, 2 = west, 3 = north, and 4 = east; level of education could be coded as 1 = college graduate and 0 = not college graduate. The MANOVA procedure will produce the main effects for each of the factors, as well as the interaction between the factors. For this example, three new dependent variables will be created to maximize group differences: one dependent variable to maximize the differences in geographic location and the linear combination of job satisfaction and attitudes toward work; one dependent variable to maximize the differences in education and the linear combination of job satisfaction and attitudes toward work; and another dependent variable to maximize separation among the groups for the interaction between geographic location and level of education. As in the previous designs, the factorial MANOVA produces Pillai's trace, Wilks's Λ , Hotelling's trace, and Roy's largest root. The multiple levels in factorial designs may produce slightly different values for the test statistics, even though these differences do not usually affect statistical significance. Wilks's Λ , associated F statistic, degrees of freedom, and the p value are usually reported in publications.

K Group MANOVA

MANOVA designs with three or more groups are known as K group MANOVAs. Like other multivariate designs, the null hypothesis tests whether differences between the mean vectors of K groups on the combination of dependent variables are due to chance. As with the factorial design, the K group MANOVA produces the main effects for each factor, as well as the interactions between factors. The same statistical tests and reporting requirements apply to the K group situation as to the factorial MANOVA.

Doubly Multivariate Designs

The purpose of doubly multivariate studies is to test for statistically significant group differences over time across a set of response variables measured at each time while accounting for the correlation among responses. A design would be considered doubly multivariate when

multiple conceptually dissimilar dependent variables are measured across multiple time periods, as in a repeated measures study. For example, a study to compare problem-solving strategies of intrinsically and extrinsically motivated learners in different test situations could involve two dependent measures (score on a mathematics test and score on a reading test) taken at three different times (before a unit of instruction on problem solving, immediately following the instruction, and 6 weeks after the instruction) for each participant. Type of learner and test situation would be between-subjects factors and time would be a within-subjects factor.

Multivariate Analysis of Covariance

A blend of analysis of covariance and MANOVA, called multivariate analysis of covariance (MANCOVA) allows the researcher to control for the effects of one or more covariates. MANCOVA allows the researcher to control for sources of variation within multiple variables. In the earlier example on attitudes toward the environment, the effects of concomitant variables such as number of people living in a household, age of head of household, gender, annual income, and education level can be statistically removed from the analysis with MANCOVA.

Factor Analysis

MANOVA is useful as a data reduction procedure to condense a large number of variables into a smaller, more definitive set of hypothetical constructs. This procedure is known as *factor analysis*. Factor analysis is especially useful in survey research to reduce a large number of variables (survey items) to a smaller number of hypothetical variables by identifying variables that group or cluster together. For example, two or more dependent variables in a data set may measure the same entity or construct. If this is the case, the variables may be combined to form a new hypothetical variable. For example, a survey of students' attitudes toward work may include 40 related items, whereas a factor analysis may reveal three underlying hypothetical constructs.

Discriminant Analysis

A common use of discriminant analysis (DA) is prediction of group membership by maximizing the linear combination of multiple quantitative independent variables that best portrays differences among groups. For example, a college may wish to group incoming students based on their likelihood of being graduated. This is called predictive DA. Also, DA is used to describe differences among groups by identifying *discriminant functions* based on uncorrelated linear

combinations of the independent variables. This technique may be useful following a MANOVA analysis and is called descriptive DA.

MULTIVARIATE NORMAL DISTRIBUTION

One of the most familiar distributions in statistics is the normal or Gaussian distribution. It has two parameters, corresponding to the first two moments (mean and variance). Once these parameters are known, the distribution is completely specified. The multivariate normal distribution is a generalization of the normal distribution and also has a prominent role in probability theory and statistics. Its parameters include not only the means and variances of the individual variables in a multivariate set but also the correlations between those variables. The success of the multivariate normal distribution is due to its mathematical tractability and to the *multivariate central limit theorem*, which states that the sampling distributions of many multivariate statistics are

normal, regardless of the parent distribution. Thus, the multivariate normal distribution is very useful in many statistical problems, such as multiple linear regressions and sampling distributions.

Probability Density Function

If $\mathbf{X} = (X_1, \dots, X_n)'$ is a multivariate normal random vector, denoted $\mathbf{X} \sim N(\mu, \Sigma)$ or $\mathbf{X} \sim N_n(\mu, \Sigma)$, then its density is given by

$$f_{\mathbf{X}}(\mathbf{x}) = \frac{1}{|\Sigma|^{1/2} (2\pi)^{n/2}} \exp \left\{ -\frac{1}{2} \left((\mathbf{x} - \mu)' \Sigma^{-1} (\mathbf{x} - \mu) \right) \right\},$$

where $\mu = (\mu_1, \dots, \mu_n)' = E(\mathbf{X})$ is a vector whose components are the expectations $E(X_1), \dots, E(X_n)$ and Σ is the nonsingular variance-covariance matrix ($n \times n$) whose diagonal terms are variances and off-diagonal terms are covariances:

$$\begin{aligned} \Sigma = V(\mathbf{X}) &= [E(\mathbf{X} - \mu)(\mathbf{X} - \mu)'] \\ &= \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \cdots & \sigma_{1n} \\ \sigma_{21} & \sigma_2^2 & \cdots & \sigma_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{n1} & \sigma_{n2} & \cdots & \sigma_n^2 \end{bmatrix}. \end{aligned}$$

Note that the covariance matrix Σ is symmetric and positive definite. The (i, j) th element is given by $\sigma_{ij} = E[(X_i - \mu_i)(X_j - \mu_j)]$ and $\sigma_i^2 \equiv \sigma_{ii} = V(X_i)$.

An important special case of the multivariate normal distribution is the bivariate normal. If $\begin{pmatrix} X_1 \\ X_2 \end{pmatrix} \sim N_2(\mu, \Sigma)$, where $\mu = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix}$, $\Sigma = \begin{bmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{bmatrix}$ and $\rho \equiv \text{Corr}(X_1, X_2) = \frac{\sigma_{12}}{\sigma_1\sigma_2}$, then the bivariate density is given by

$$f_{X_1, X_2}(x, y) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \exp \left\{ -\frac{\left(\frac{x-\mu_1}{\sigma_1} \right)^2 - 2\rho \left(\frac{x-\mu_1}{\sigma_1} \right) \left(\frac{y-\mu_2}{\sigma_2} \right) + \left(\frac{y-\mu_2}{\sigma_2} \right)^2}{2(1-\rho^2)} \right\}.$$

Let $\mathbf{X} = (X_1, X_2)'$; the joint density can be rewritten in matrix notation as

$$f_{\mathbf{X}}(\mathbf{x}) = \frac{1}{2\pi|\Sigma|^{1/2}} \exp \left\{ -\frac{1}{2} \left((\mathbf{x} - \mu)' \Sigma^{-1} (\mathbf{x} - \mu) \right) \right\}.$$

Multivariate Normal Density Contours

The contour levels of $f_X(x)$, that is, the set of points in $\mathbb{R}^n$ for which $f_X(x)$ is constant, satisfy

$$(\mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu}) = c^2.$$

These surfaces are n -dimensional ellipsoids centered at $\boldsymbol{\mu}$, whose axes of symmetry are given by the principal components (the eigenvectors) of $\boldsymbol{\Sigma}$. Specifically, the length of the ellipsoid along the i th axis is $c\sqrt{\lambda_i}$, where λ_i is the i th eigenvalue associated with the eigenvector e_i (recall that eigenvectors e_i and eigenvalues λ_i are solutions to $\boldsymbol{\Sigma}e_i = \lambda_i e_i$ for $i=1, \dots, n$).

Some Basic Properties

The following list presents some important properties involving the multivariate normal distribution.

1. The first two moments of a multivariate normal distribution, namely $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ completely characterize the distribution. In other words, if $\mathbf{X}$ and $\mathbf{Y}$ are both multivariate normal with the same first two moments, then they are similarly distributed.
2. Let $\mathbf{X} = (X_1, \dots, X_n)'$ be a multivariate normal random vector with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$, and let $\boldsymbol{\alpha}' = (\alpha_1, \dots, \alpha_n) \in \mathbb{R}^n / 0$. The linear combination $Y = \boldsymbol{\alpha}'\mathbf{X} = \alpha_1 X_1 + \dots + \alpha_n X_n$ is normal with mean $E(Y) = \boldsymbol{\alpha}'\boldsymbol{\mu}$ and variance

$$V(Y) = \boldsymbol{\alpha}' \boldsymbol{\Sigma} \boldsymbol{\alpha} = \sum_{i=1}^n \alpha_i^2 V(X_i) + \sum_{i \neq j} \alpha_i \alpha_j \text{Cov}(X_i, X_j).$$

Also if $\boldsymbol{\alpha}'\mathbf{X}$ is normal with mean $\boldsymbol{\alpha}'\boldsymbol{\mu}$ and variance $\boldsymbol{\alpha}'\boldsymbol{\Sigma}\boldsymbol{\alpha}$ for all possible $\boldsymbol{\alpha}$, then $\mathbf{X}$ must be a multivariate normal random vector with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}(\mathbf{X} \sim N_n(\boldsymbol{\mu}, \boldsymbol{\Sigma}))$.

3. More generally, let $\mathbf{X} = (X_1, \dots, X_n)'$ be a multivariate normal random vector with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$, and let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a full rank matrix with $m \leq n$, the set of linear combinations $\mathbf{Y} = (Y_1, \dots, Y_m)' = \mathbf{A}\mathbf{X}$ is multivariate normally distributed with mean $\mathbf{A}\boldsymbol{\mu}$ and covariance matrix $\mathbf{A}\boldsymbol{\Sigma}\mathbf{A}'$. Also, if $\mathbf{Y} = \mathbf{A}\mathbf{X} + \mathbf{b}$ where $\mathbf{b}$ is a $m \times 1$ vector of constants, then $\mathbf{Y}$ is multivariate normally distributed with mean $\mathbf{A}\boldsymbol{\mu} + \mathbf{b}$ and covariance matrix $\mathbf{A}\boldsymbol{\Sigma}\mathbf{A}'$.
4. If X_i and Y_j are jointly normally distributed, then they are independent if and only if $\text{Cov}(Y_i, Y_j) = 0$. Note that it is not necessarily true that uncorrelated univariate normal random variables are independent. Indeed, two random variables that are marginally normally distributed may fail to be jointly normally distributed.

5. Let $\mathbf{Z} = (Z_1, \dots, Z_n)'$ where $Z_i \stackrel{i.i.d.}{\sim} N(0, 1)$ (where i.i.d. = independent and identically distributed). $\mathbf{Z}$ is said to be standard multivariate normal, denoted $\mathbf{Z} \sim N(0, \mathbf{I}_n)$, and it can be shown that $E[\mathbf{Z}] = 0$ and $V(\mathbf{Z}) = \mathbf{I}_n$, where $\mathbf{I}_n$ denotes the unit matrix of order n . The joint density of vector $\mathbf{Z}$ is given by

$$f_{\mathbf{Z}}(\mathbf{z}) = \prod_{i=1}^n f_{Z_i}(z_i) = (2\pi)^{-n/2} \exp\left\{-\frac{1}{2}\mathbf{z}'\mathbf{z}\right\}.$$

The density $f_{\mathbf{Z}}(\mathbf{z})$ is symmetric and unimodal with mode equal to zero. The contour levels of $f_{\mathbf{Z}}(\mathbf{z})$, that is, the set of points in $\mathbb{R}^n$ for which $f_{\mathbf{Z}}(\mathbf{z})$ is constant, are defined by

$$\mathbf{z}'\mathbf{z} = \sum_{i=1}^n z_i^2 = c^2,$$

where $c \geq 0$. The contour levels of $f_{\mathbf{Z}}(\mathbf{z})$ are concentric circles in $\mathbb{R}^n$ centered at zero.

6. If $Y_1, \dots, Y_n \sim \text{ind}N(\mu_i, \sigma_i^2)$, then $\sigma_{ij} = 0$ for all $i \neq j$, and it follows that $\boldsymbol{\Sigma}$ is a diagonal matrix. Thus, if

$$\boldsymbol{\Sigma} = \begin{pmatrix} \sigma_1^2 & 0 & \dots & 0 \\ 0 & \sigma_2^2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \sigma_n^2 \end{pmatrix},$$

then

$$\boldsymbol{\Sigma} = \begin{pmatrix} 1/\sigma_1^2 & 0 & \dots & 0 \\ 0 & 1/\sigma_2^2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1/\sigma_n^2 \end{pmatrix},$$

so that

$$(\mathbf{y} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{y} - \boldsymbol{\mu}) = \sum_{j=1}^n (y_j - \mu_j)^2 / \sigma_j^2.$$

Note also that, as $\boldsymbol{\Sigma}$ is diagonal, we have

$$|\boldsymbol{\Sigma}| = \sigma_1^2 \sigma_2^2 \dots \sigma_n^2.$$

The joint density becomes

$$\begin{aligned} f_{\mathbf{Y}}(\mathbf{y}) &= \prod_{i=1}^n f_{Y_i}(y_i; \mu_i, \sigma_i^2) \\ &= \prod_{i=1}^n \frac{1}{\sigma_i \sqrt{2\pi}} \exp\left\{-\frac{1}{2}\left(\frac{y_i - \mu_i}{\sigma_i}\right)^2\right\}. \end{aligned} \quad \$$$

Thus, $f_Y(y)$ reduces to the product of univariate normal densities.

Moment Generating Function

Let $\mathbf{Z} = (Z_1, \dots, Z_n)'$ where $Z_i \stackrel{i.i.d.}{\sim} N(0, 1)$. As previously seen, $\mathbf{Z} \sim N(\mathbf{0}, \mathbf{I}_n)$, is referred to as a standard multivariate normal vector, and the density of $\mathbf{Z}$ is given by

$$f_Z(\mathbf{z}) = (2\pi)^{-n/2} \exp\left\{-\frac{1}{2}\mathbf{z}'\mathbf{z}\right\}.$$

The moment generating function of $\mathbf{Z}$ is obtained as follows:

$$\begin{aligned} M_Z(\mathbf{t}) &= E[e^{\mathbf{t}'\mathbf{Z}}] = (2\pi)^{-n/2} \int_{\mathbb{R}^n} \exp\{\mathbf{t}'\mathbf{z} - \mathbf{z}'\mathbf{z}/2\} d\mathbf{z} \\ &= \prod_{i=1}^n \int_{-\infty}^{+\infty} \frac{1}{\sqrt{2\pi}} \exp\left\{t_i z_i - \frac{1}{2}z_i^2\right\} dz_i \\ &= \prod_{i=1}^n M_{Z_i}(t_i) \\ &= E[e^{t_1 Z_1}] E[e^{t_2 Z_2}] \dots E[e^{t_n Z_n}] \\ &= \exp\left\{\frac{1}{2}t_1^2\right\} \exp\left\{\frac{1}{2}t_2^2\right\} \dots \exp\left\{\frac{1}{2}t_n^2\right\} \\ &= \exp\left\{\frac{1}{2}\sum_{i=1}^n t_i^2\right\} \\ &= \exp\left\{\frac{1}{2}\mathbf{t}'\mathbf{t}\right\} \end{aligned}$$

To obtain the moment generating function of the generalized location-scale family, let $\mathbf{X} = \{\mu + \Sigma^{1/2} \mathbf{Z}$ where $\Sigma^{1/2} \Sigma^{1/2} = \Sigma$ ($\Sigma^{1/2}$ is obtained via the Cholesky decomposition of Σ) so that $\mathbf{X} \sim N_n(\mu, \Sigma)$. Hence,

$$\begin{aligned} M_X(\mathbf{t}) &= E[e^{\mathbf{t}'\mathbf{X}}] \\ &= E\left[\exp\left\{\mathbf{t}'\mu + \mathbf{t}'\Sigma^{1/2}\mathbf{Z}\right\}\right] \\ &= e^{\mathbf{t}'\mu} E\left[\exp\left\{\mathbf{t}'\Sigma^{1/2}\mathbf{Z}\right\}\right] \\ &= e^{\mathbf{t}'\mu} M_Z\left(\left(\Sigma^{1/2}\right)' \mathbf{t}\right) \\ &= e^{\mathbf{t}'\mu} \exp\left\{\frac{1}{2}\left(\left(\Sigma^{1/2}\right)' \mathbf{t}\right)' \left(\Sigma^{1/2}\right)' \mathbf{t}\right\} \\ &= \exp\left\{\mathbf{t}'\mu + \frac{1}{2}\mathbf{t}'\Sigma\mathbf{t}\right\}. \end{aligned}$$

Simulation

To generate a sample of observations from a random variable $\mathbf{Z} \sim N(\mathbf{0}, \mathbf{I}_n)$, one should note that each of the n components of vector $\mathbf{Z}$ is independent and identically distributed standard univariate normal, for which simulation methods are well known. Let $\mathbf{X} = \mu + \Sigma^{1/2}\mathbf{Z}$ where $\Sigma^{1/2} \Sigma^{1/2} = \Sigma$ so that $\mathbf{X} \sim N_n(\mu, \Sigma)$. Realizations of $\mathbf{X}$ can be obtained from the generated samples $\mathbf{z}$ as $\{\mu + \Sigma^{1/2}\mathbf{z}$ where $\Sigma^{1/2}$ can be computed via the Cholesky decomposition.

Cumulative Distribution Function

The cumulative distribution function is the probability that all values in the random vector $\mathbf{X}$ are less than or equal to the values in the random vector $\mathbf{x}$ ($\Pr(\mathbf{X} \leq \mathbf{x})$). Although there is no closed form for the cumulative distribution function of the multivariate normal, it can be calculated numerically by generating a large sample of observations and computing the fraction that satisfies $\mathbf{X} \leq \mathbf{x}$.

Marginal Distributions

Let $\mathbf{Y} = (Y_1, \dots, Y_n)'$ $\sim N(\mu, \Sigma)$. Suppose that $\mathbf{Y}$ is partitioned into two subvectors, $\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$, so that we can write $\mathbf{Y} = (\mathbf{Y}_{(1)}, \mathbf{Y}_{(2)})'$, where $\mathbf{Y}_{(1)} = (Y_1, \dots, Y_p)'$ and $\mathbf{Y}_{(2)} = (Y_{p+1}, \dots, Y_n)'$. Let μ and Σ be independent and identically distributed partitioned accordingly, that is, $\mu = (\mu'_{(1)}, \mu'_{(2)})'$ and

$$\Sigma = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}, \quad \Sigma_{21} = \Sigma'_{12},$$

Where $\mu_{(i)} = E[\mathbf{Y}_{(i)}]$, $\Sigma_{ii} = V[\mathbf{Y}_{(i)}]$, $i = 1, 2$, and $\Sigma_{12} = \text{Cov}(\mathbf{Y}_{(1)}, \mathbf{Y}_{(2)})$.

Then, it can be shown that the distributions of the two subvectors $\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$ are multivariate normal, defined as follows:

$$\mathbf{Y}_{(1)} \sim N(\mu_{(1)}, \Sigma_{11}) \text{ and } \mathbf{Y}_{(2)} \sim N(\mu_{(2)}, \Sigma_{22}).$$

This result means that

- Each of the Y_i s is univariate normal.
- All possible subvectors are multivariate normal.
- All marginal distributions are multivariate normal.

Moreover, if $\Sigma_{12} = 0$ ($\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$ are uncorrelated), then $\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$ are statistically independent. Recall that the covariance of two independent random

variables is always zero but the opposite need not be true. Thus, $\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$ are statistically independent if and only if $\Sigma_{12} = \Sigma'_{12} = 0$.

Conditional Normal Distributions

Let $\mathbf{Y} = (Y_1, \dots, Y_n)' \sim N(\boldsymbol{\mu}, \Sigma)$. Suppose that $\mathbf{Y}$ is partitioned into two subvectors, $\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$, in the same manner as in the previous section.

The conditional distribution of $\mathbf{Y}_{(1)}$ given $\mathbf{Y}_{(2)}$ is multivariate normal characterized by its mean and covariance matrix as follows:

$$\begin{aligned} & \mathcal{N}(\mathbf{Y}_{(1)} | \mathbf{Y}_{(2)} = \mathbf{y}_{(2)}) \Sigma \\ & \mathcal{N}(\boldsymbol{\mu}_{(1)} + \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{y}_{(2)} - \boldsymbol{\mu}_{(2)}), \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}). \end{aligned}$$

To verify this, let $\mathbf{X} = \mathbf{Y}_{(1)} - \boldsymbol{\mu}_{(1)} - \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{Y}_{(2)} - \boldsymbol{\mu}_{(2)})$. As a linear combination of the elements of $\mathbf{Y}$, $\mathbf{X}$ is also normally distributed with mean zero and variance $V(\mathbf{X}) = E[\mathbf{X}\mathbf{X}']$, given by:

$$\begin{aligned} E[\mathbf{X}\mathbf{X}'] &= E\left[\left\{(\mathbf{Y}_{(1)} - \boldsymbol{\mu}_{(1)}) - \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{Y}_{(2)} - \boldsymbol{\mu}_{(2)})\right\} \right. \\ & \quad \left. \times \left\{(\mathbf{Y}_{(1)} - \boldsymbol{\mu}_{(1)})' - (\mathbf{Y}_{(2)} - \boldsymbol{\mu}_{(2)})' \Sigma_{22}^{-1} \Sigma_{12}\right\}\right] \\ &= \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21} \\ & \quad + \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{22} \Sigma_{22}^{-1} \Sigma_{21} \\ &= \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}. \end{aligned}$$

Moreover, if we consider $(\mathbf{X}', \mathbf{Y}_{(2)}')'$, which is also multivariate normal, we obtain the following covariance term:

$$\begin{aligned} & E[(\mathbf{X} - 0)(\mathbf{Y}_{(2)} - \boldsymbol{\mu}_{(2)})'] \\ &= E\left[(\mathbf{Y}_{(1)} - \boldsymbol{\mu}_{(1)} - \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{Y}_{(2)} - \boldsymbol{\mu}_{(2)})) \right. \\ & \quad \left. (\mathbf{Y}_{(2)} - \boldsymbol{\mu}_{(2)})'\right] = \Sigma_{12} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{22} = 0. \end{aligned}$$

This implies that $\mathbf{X}$ and $\mathbf{Y}_{(2)}$ are independent, and we can write

$$\begin{bmatrix} \mathbf{X} \\ \mathbf{Y}_{(2)} \end{bmatrix} \sim N\left(\begin{bmatrix} 0 \\ \boldsymbol{\mu}_{(2)} \end{bmatrix}, \begin{bmatrix} \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21} & 0 \\ 0 & \Sigma_{22} \end{bmatrix}\right).$$

As

$$\mathbf{Y}_{(1)} = \mathbf{X} + \boldsymbol{\mu}_{(1)} + \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{Y}_{(2)} - \boldsymbol{\mu}_{(2)}),$$

conditional on $\mathbf{Y}_{(2)} = \mathbf{y}_{(2)}$, $\mathbf{Y}_{(1)}$ is normally distributed with mean

$$\underbrace{E(\mathbf{X})}_0 + \boldsymbol{\mu}_{(1)} + \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{y}_{(2)} - \boldsymbol{\mu}_{(2)})$$

and variance $V(\mathbf{X}) = \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}$.

In the bivariate normal case, we replace $\mathbf{Y}_{(1)}$ and $\mathbf{Y}_{(2)}$ by $Y_{(1)}$ and $Y_{(2)}$ and the conditional distribution of Y_1 given Y_2 is normal as follows:

$$\begin{aligned} & Y_1 | (Y_2 = y_2) \sim \\ & N\left(\mu_1 + \rho \frac{\sigma_1}{\sigma_2} (y_2 - \mu_2), \sigma_1^2 (1 - \rho^2)\right). \end{aligned}$$

Another special case is with $\mathbf{Y}_{(1)} = Y_1$ and $\mathbf{Y}_{(2)} = (Y_2, \dots, Y_n)'$ so that

$$\begin{aligned} & (Y_1 | \mathbf{Y}_{(2)} = \mathbf{y}_{(2)}) \sim \\ & N(\mu_1 + \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{y}_{(2)} - \boldsymbol{\mu}_{(2)}), \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}). \end{aligned}$$

The mean of this particular conditional distribution $\mu_1 + \Sigma_{12} \Sigma_{22}^{-1} (\mathbf{y}_{(2)} - \boldsymbol{\mu}_{(2)})$ is referred to as a multiple regression function of Y_1 on $\mathbf{Y}_{(2)}$, with the regression coefficient vector being $\boldsymbol{\beta} = \Sigma_{12} \Sigma_{22}^{-1}$.

Partial Correlation

Let $\mathbf{Y} = (Y_1, \dots, Y_n)' \sim N(\boldsymbol{\mu}, \Sigma)$. The covariance (correlation) between two of the univariate random variables in $\mathbf{Y}$, say Y_i and Y_j , is determined from the (i, j) th entry of Σ . The partial correlation concept considers the correlation of Y_i and Y_j when conditioning on a set of other variables in $\mathbf{Y}$. Let $C = \Sigma_{11} - \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}$ which is the variance of the conditional distribution of $Y_{(1)}$ given $\mathbf{Y}_{(2)} = \mathbf{y}_{(2)}$, and denote the (i, j) th element of C by $\sigma_{ij|p+1, \dots, n}$ where p is the dimension of the vector $\mathbf{Y}_{(1)}$.

The partial correlation of Y_i and Y_j , given $\mathbf{Y}_{(2)}$, is defined by

$$\rho_{ij|p+1, \dots, n} = \frac{\sigma_{ij|p+1, \dots, n}}{\sqrt{\sigma_{ii|p+1, \dots, n} \sigma_{jj|p+1, \dots, n}}}.$$

Testing for Multivariate Normality

If a vector is multivariate normally distributed, each individual component follows a univariate Gaussian distribution. However, univariate normality of each variable in a set is not sufficient for multivariate normality. Therefore, to test the adequacy of the multivariate normality assumption, several authors have presented a battery of tests consistent with the multivariate framework. For this purpose, Kanti V. Mardia proposed multivariate extensions of the skewness and kurtosis statistics, which are extensively used in the univariate framework to test for normality.

Let $\{\mathbf{X}_i\}_{i=1}^m = \{X_{1i}, \dots, X_{ni}\}_{i=1}^m$ be the i th random sample from an n -variate distribution, $\bar{\mathbf{X}}$ the vector of

sample means, and S_X the sample covariance matrix. The n -variate skewness and kurtosis statistics denoted respectively by $b_{1,n}$ and $b_{2,n}$ are defined as follows:

$$b_{1,n} = \frac{1}{m^2} \sum_{i=1}^m \sum_{j=1}^m \left((\mathbf{X}_i - \bar{\mathbf{X}})' S_X^{-1} (\mathbf{X}_j - \bar{\mathbf{X}}) \right)^3$$

$$b_{2,n} = \frac{1}{m} \sum_{i=1}^m \left((\mathbf{X}_i - \bar{\mathbf{X}})' S_X^{-1} (\mathbf{X}_i - \bar{\mathbf{X}}) \right)^2.$$

We can verify that these statistics reduce to the well-known univariate skewness and kurtosis for $n = 1$.

Based of their asymptotic distributions, the multivariate skewness and kurtosis defined above can be used to test for multivariate normality. If $\mathbf{X}$ is multivariate normal, then $b_{1,n}$ and $b_{2,n}$ have expected values 0 and $n(n+2)/6$. It can be also shown that for large m , the limiting distribution of $(m/6)b_{1,n}$ is a chi square with $n(n+1)(n+2)/6$ degrees of freedom, and the limiting distribution of $\sqrt{m}(b_{2,n} - n(n+2)/6)$ is $N(0,1)$.

The Gaussian Copula Function

Recently in multivariate modeling, much attention has been paid to copula functions. A copula is a function that links an n -dimensional distribution function to its one-dimensional margins and is itself a continuous distribution function characterizing the dependence structure of the model. Sklar's theorem states that under appropriate conditions, the joint density can be written as a product of the marginal densities and the copula density. Several copula families are available that can incorporate the relationships between random variables. Among these families, the Gaussian copula encodes dependence in precisely the same way as the multivariate normal distribution does, using only pairwise correlations among the variables. However, it does so for variables with arbitrary margins. A multivariate normal distribution arises whenever univariate normal margins are linked through a Gaussian copula. The Gaussian copula function is defined by

$$C(u_1, u_2, \dots, u_n) = \Phi_p^n \left(\Phi^{-1}(u_1), \Phi^{-1}(u_2), \dots, \Phi^{-1}(u_n) \right),$$

where Φ_p^n denotes the joint distribution function of the n -variate standard normal distribution with linear correlation matrix ρ , and Φ^{-1} denotes the inverse of the univariate standard normal distribution function. In the bivariate case, the copula expression can be written as

$$C(u, v) = \int_{-\infty}^{\Phi^{-1}(u)} \int_{-\infty}^{\Phi^{-1}(v)} \frac{1}{2\pi\sqrt{1-\rho^2}} \exp \left\{ -\frac{1}{2} \frac{x^2 - 2\rho xy + y^2}{(1-\rho^2)} \right\} dx dy,$$

where ρ is the usual linear correlation coefficient of the corresponding bivariate normal distribution.

Multiple Linear Regression and Sampling Distribution

In this section, the multiple regression model and the associated sampling distribution are presented as an illustration of the usefulness of the multivariate normal distribution in statistics.

Consider the following multiple linear regression model:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_q X_q + \varepsilon,$$

where Y is the response variable, $(X_1, X_2, \dots, X_q)'$ is a vector representing a set of q explanatory variables, and ε is the error term. Note that the simple linear regression model is a special case with $q = 1$.

Suppose that we have n observations on Y and on each of the explanatory variables, that is,

$$\begin{aligned} Y_1 &= \beta_0 + \beta_1 X_{11} + \beta_2 X_{12} + \dots + \beta_q X_{1q} + \varepsilon_1 \\ Y_2 &= \beta_0 + \beta_1 X_{21} + \beta_2 X_{22} + \dots + \beta_q X_{2q} + \varepsilon_2 \\ &\vdots \\ Y_n &= \beta_0 + \beta_1 X_{n1} + \beta_2 X_{n2} + \dots + \beta_q X_{nq} + \varepsilon_n, \end{aligned}$$

where $E(\varepsilon_i) = 0$, $\text{Var}(\varepsilon_i) = \sigma^2$ and $(\varepsilon_i, \varepsilon_j) = 0$ for $i \neq j$. We can rewrite

$$\begin{pmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_n \end{pmatrix} = \begin{pmatrix} 1 & X_{11} & X_{12} & \dots & X_{1q} \\ 1 & X_{21} & X_{22} & \dots & X_{2q} \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & X_{n1} & X_{n2} & \dots & X_{nq} \end{pmatrix} \begin{pmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \vdots \\ \beta_q \end{pmatrix} + \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \varepsilon_n \end{pmatrix}$$

or else

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$$

$$E(\boldsymbol{\varepsilon}) = 0 \text{ and } \text{cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}_n.$$

Note that in the previous expression, ε is a multivariate normal random vector whereas $\mathbf{X}\boldsymbol{\beta}$ is a vector of constants. Thus, $\mathbf{Y}$ is a linear combination of a multivariate normally distributed vector. It follows that $\mathbf{Y}$ is also multivariate normal with mean $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ and covariance $\text{cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}_n$.

The goal of an analysis of data of this form is to estimate the regression parameter $\boldsymbol{\beta}$. The least squares estimate of $\boldsymbol{\beta}$ is found by minimizing the sum of squared deviations

$$\sum_{j=1}^n (Y_j - \beta_0 - \beta_1 X_{j1} + \beta_2 X_{j2} + \cdots + \beta_q X_{jq})^2.$$

In matrix terms, this sum of squared deviations may be written

$$(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})' (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}) = \varepsilon' \varepsilon.$$

If $\mathbf{X}$ is of full rank, then the least squares estimator for $\boldsymbol{\beta}$ is given by

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{Y}.$$

It is of interest to characterize the probability distribution of an estimator. If we refer to the multiple regression problem, the estimator $\hat{\boldsymbol{\beta}}$ depends on the response $\mathbf{Y}$. Therefore, the properties of its distribution will depend on those of $\mathbf{Y}$. More specifically the distribution of $\hat{\boldsymbol{\beta}}$ is multivariate normal as follows:

$$\hat{\boldsymbol{\beta}} \sim N(\boldsymbol{\beta}, \sigma^2 (\mathbf{X}'\mathbf{X})^{-1}).$$

This result can be used to obtain estimated standard errors for the components of $\hat{\boldsymbol{\beta}}$, that is, estimates of the standard deviation of the sampling distributions of each component of $\hat{\boldsymbol{\beta}}$.

Reader's Guide

The Reader's Guide is provided to assist readers in locating articles on related topics. It classifies articles into 31 general topical categories: Bayesian Statistics; Descriptive Statistics; Distributions; Graphical Displays of Data; Hypothesis Testing; Important Publications; Inferential Statistics; Item Response Theory; Mathematical Concepts; Measurement Concepts; Organizations; Publishing; Qualitative Research; Reliability of Scores; Research Design Concepts; Research Designs; Research Ethics; Research Process; Research Validity Issues; Sampling; Scaling; Social Network Analysis; Software Applications; Statistical Assumptions; Statistical Concepts; Statistical Procedures; Statistical Tests; Structural Equation Modeling; Theories, Laws, and Principles; Types of Variables; and Validity of Scores. Entries may be listed under more than one topic.

Bayesian Statistics

Bayes's Theorem
Bayesian Adaptive Randomization Design
Bayesian Data Analysis
Bayesian Information Criterion
Bayesian Network Analysis
Posterior Distribution

Descriptive Statistics

Central Tendency, Measures of
Cohen's d Statistic
Cohen's f Statistic
Correspondence Analysis
Descriptive Statistics
Effect Size, Measures of
Eta-Squared
Factor Loadings
Mean
Median
Mode
Partial Eta-Squared

NAME GENERATOR

A name generator is an instrument that is used to collect the names of alters in social network analysis. The collected names are the crucial basis for two subsequent data collection steps in social network analysis: *name interpretation* and *name interrelation*. Name generators use a fixed-choice or a free-choice approach. Different name generator formats also exist. This entry examines the purpose of name generators, prerequisites, design options, formats, alternative generators, and subsequent steps.

Purpose

Through means of a name generator, the researcher asks the respondent (ego) to provide a list of the names of other actors (alters) who are relevant to the investigated network by, for example, having a particular relationship with the ego (e.g., friendship). Depending on the research aim and definition of the network, alters can be human individuals, objects, animals, and similar groupings.

In general, name generators ask questions about “who” is in the network. Some questions that are used for name generation are “who were your friends when you were a child?” or “with whom did you have contact in the last two days?” Several name generators can be used during data collection, for it might be the case that the alters in question differ depending on the research aim and number of questions. If the researchers plan to publish the data collected through a name generator, they should ensure alter anonymity. To achieve this, they can use nicknames or initials.

Prerequisites and Design

Before applying a name generator, careful considerations of the network’s boundary and the sample should be taken. The choice of name generator(s) influences the reliability and validity of the network measures. If the questions in the name generators are framed inaccurately, this will have direct implications for the quality of the data. For example, important alters might be left out, thus limiting the data’s expressiveness.

Name generators use a fixed-choice or free-choice approach, depending on the network’s boundary, the research aim, and the sample. It might be the case that the number of alters in a network that could possibly be nominated is too large, and it would be too demanding for the respondent to name them all. Therefore, a fixed-choice approach collects a predefined number of alters; an exemplary question for the name generator is “who are your five best friends?” Fixed-choice approaches are more commonly used in sociocentric network analysis, when the network’s boundary is already predefined and it is well-known who is part of the network. If the boundary is not clearly defined or the researcher wants to collect an exact number of alters, a free-choice approach can be used. In a free-choice name generator, the number of alters is unlimited. This approach is typically used in egocentric network analysis to define the network’s boundary.

Formats

Name generators can be applied in various formats. A paper–pencil questionnaire list, where the alters’ names can be entered, might be the most common one. Therefore, matrices are often used to proceed with

name interpretation and name interrelation. The alters' names are listed on the vertical axis and the name interpretation and name interrelation questions are listed on the horizontal axis. In interviews, names are generated through name-generating questions asked by the interviewer. The interviewer should ensure that the names are captured somewhere to prevent the exclusion of important data. Interviews can also be combined with network mapping approaches. In a mapping approach, the respondent is provided a network map to add alters to (e.g., concentric circle mapping). Archival data can also be used for name generation. In these cases, written documents or Internet data is used to generate a list of alters instead of asking individuals for names.

Alternative Generators

Besides name generators, there are similar kinds of generators that focus on specific alter characteristics rather than collecting their names. *Role generators* focus on the particular roles alters have in a network (e.g., whether family members, teachers, or peers have a particular relationship with the ego). *Position generators* examine an individual's network according to the positions alters in the network possess, such as whether alters with a low or high occupation in a company have a specific relationship with the ego. *Resource generators* investigate an individual's network by directly addressing the social resources in that network. In a matrix, the particular resources provided are listed on the vertical axis and the different alters that might be relevant to these resources are listed on the horizontal axis. The respondent can then choose which alters are relevant to a specific resource.

Subsequent Steps

Applying name generators is often the first phase in social network analysis and sets the basis for the next steps in data collection. These steps are *name interpretation* and *name interrelation*. Both are necessary to social network analysis. Name interpretation examines attributional alter data (e.g., age or gender) and is used to receive more detailed information about alters. Name interrelation focuses on the relationships between the ego and an alter or among alters. For example, a researcher might be interested in why a relationship was maintained or lost. During name interrelation, the researcher might then ask the ego whether that relationship was "weak" or "strong."

NARRATIVE RESEARCH

Narrative research aims to explore and conceptualize human experience as it is represented in textual form. Aiming for an in-depth exploration of the meanings people assign to their experiences, narrative researchers work with small samples of participants to obtain rich and free-ranging discourse. The emphasis is on storied experience. Generally, this takes the form of interviewing people around the topic of interest, but it might also involve the analysis of written documents. Narrative research as a mode of inquiry is used by researchers from a wide variety of disciplines, which include anthropology, communication studies, cultural studies, economics, education, history, linguistics, medicine, nursing, psychology, social work, and sociology. It encompasses a range of research approaches including ethnography, phenomenology, grounded theory, narratology, action research, and literary analysis, as well as such interpretive stances as feminism, social constructionism, symbolic interactionism, and psychoanalysis. This entry discusses several aspects of narrative research, including its epistemological grounding, procedures, analysis, products, and advantages and disadvantages.

Epistemological Grounding

The epistemological grounding for narrative research is on a continuum of postmodern philosophical ideas in that there is a respect for the relativity and multiplicity

of truth in regard to the human sciences. Narrative researchers rely on the epistemological arguments of such philosophers as Paul Ricoeur, Martin Heidegger, Edmund Husserl, Wilhelm Dilthey, Ludwig Wittgenstein, Mikhail Bakhtin, Jean-François Lyotard, and Hans-Georg Gadamer. Although narrative researchers differ in their view of the possibility of objectively conceived “reality,” most agree with Donald Spence’s distinction between narrative and historical truth. Factuality is of less interest than how events are understood and organized, and all knowledge is presumed to be socially constructed.

Ricoeur, in his seminal work *Time and Narrative*, argues that time is organized and experienced narratively; narratives bring order and meaning to the constantly changing flux. In its simplest form, our experience is internally ordered as “this happened, then that happened” with some (often causal) connecting link in between. Narrative is also central to how we conceive of ourselves; we create stories of ourselves to connect our actions, mark our identity, and distinguish ourselves from others.

Questions about *how* people construct themselves and others in various contexts, under various conditions, are the focus of narrative research. Narrative research paradigms, in contrast to hypothesis-testing ones, have as their aims describing and understanding rather than measuring and predicting, focusing on meaning rather than causation and frequency, interpretation rather than statistical analysis, and recognizing the importance of language and discourse rather than reduction to numerical representation. These approaches are holistic rather than atomistic, concern themselves with particularity rather than universals, are interested in the cultural context rather than trying to be context-free, and give overarching significance to subjectivity rather than questing for some kind of objectivity.

Narrative research orients itself toward understanding human complexity, especially in those cases where the many variables that contribute to human life cannot be controlled. Narrative research aims to take into account—and interpretively account for—the multiple perspectives of *both* the researched and researcher.

Jerome Bruner has most championed the legitimization of what he calls “narrative modes of knowing,” which privileges the particulars of lived experience rather than constructs about variables and classes. It aims for the understanding of lives in context rather than through a prefigured and narrowing lens. Meaning is not inherent in an act or experience but is constructed through social discourse. Meaning is generated by the linkages the participant makes between aspects of the life he or she is living and by the explicit linkages the researcher makes between this understanding and

interpretation, which is meaning constructed at another level of analysis.

Life Is a Story

One major presupposition of narrative research is that humans experience their lives in emplotted forms resembling stories or at least communicate about their experiences in this way. People use narrative as a form of constructing their views of the world; time itself is constructed narratively. Important events are represented as taking place through time, having roots in the past, and extending in their implications into the future. Life narratives are also contextual in that persons act within situational contexts that are both immediate and more broadly societal. The focus of research is on what the individuals think they are doing and why they think they are doing so. Behavior, then, is always understood in the individual’s context, however he or she might construct it. Thus, narratives can be examined for personal meanings, cultural meanings, and the interaction between these.

Narrative researchers invite participants to describe in detail—tell the story of—either a particular event or a significant aspect or time of life (e.g., a turning point), or they ask participants to narrate an entire life story. Narration of experience, whether of specific events or entire life histories, involves the subjectivity of the actor, with attendant wishes, conflicts, goals, opinions, emotions, worldviews, and morals, all of which are open to the gaze of the researcher. Such narratives also either implicitly or explicitly involve settings that include those others who are directly involved in the events being related and also involve all those relationships that have influenced the narrator in ever-widening social circles. The person is assumed to be speaking from a specific position in culture and in historical time. Some of this positionality is reflected in the use of language and concepts with which a person understands her or his life. Other aspects of context are made explicit as the researcher is mindful of the person’s experience of herself or himself in terms of gender, race, culture, age, social class, sexual orientation, nationality, and the like. Participants are viewed as unique individuals with particularity in terms of social location; a person is not viewed as representative of some universal and interchangeable, randomly selected “subject.”

People, however, do not “have” stories of their lives; they create them for the circumstance in which the story will be told. No two interviewers will obtain exactly the same story from an individual interviewee. Therefore, a thoroughly reflexive analysis of the parameters and influences on the interview situation replaces concern with reliability.

A narrative can be defined as a story of a sequence of events. Narratives are organized so as to place meanings retrospectively on events, with events described in such a way as to express the meanings the narrator wishes to convey. Narrative is a way of understanding one's own (and others') action, of organizing personal experience, both internal and external, into a meaningful whole. This involves attributing agency to the characters in the narrative and inferring causal links between the events. In the classic formulation, a narrative is an account with three components: a beginning, a middle, and an end. William Labov depicts all narratives as having clauses that orient the reader to the story, tell about the events, or evaluate the story—that is, instruct the listener or reader as to how the story is to be understood. The evaluation of events is of primary interest to the narrative researcher because this represents the ways in which the narrator constructs a meaning (or set of meanings) within the narrative. Such meanings, however, are not viewed to be either singular or static. Some narrative theorists have argued that the process of creating an autobiographical narrative is itself transforming of self because the self that is fashioned in the present extends into the future. Thus, narrative research is viewed to be investigating a self that is alive and evolving, a self that can shift meanings, rather than a fixed entity.

Narrative researchers might also consider the ways in which the act of narration is performative. Telling a story constructs a self and might be used to accomplish a social purpose such as defending the self or entertaining someone. Thus, the focus is not only on the content of what is communicated in the narrative but also on how the narrator constructs the story and the social locations from which the narrator speaks. Society and culture also enable and constrain certain kinds of stories; meaning making is always embedded in the concepts that are culturally available at a particular time, and these might be of interest in a narrative research project. Narrative researchers, then, attend to the myriad versions of self, reality, and experience that the storyteller produces through the telling.

Procedures

Narrative research begins with a conceptual question derived from existing knowledge and a plan to explore this question through the narratives of people whose experience might illuminate the question. Most narrative research involves personal interviews, most often individual, but sometimes in groups. Some narrative researchers might (also) use personal documents such as journals, diaries, memoirs, or films as bases for their analyses. Narrative research uses whatever storied

materials are available or can be produced from the kinds of people who might have personal knowledge and experiences to bring to bear on the research question.

In interview-based designs, which are the most widespread form of narrative research, participants who fit into the subgroup of interest are invited to be interviewed at length (generally 1–4 hours). Interviews are recorded and then transcribed. The narrative researcher creates “experience-near” questions related to the conceptual question that might be used to encourage participants to tell about their experiences. This might be a request for a full life story or it might be a question about a particular aspect of life experience such as life transitions, important relationships, or responses to disruptive life events.

Narrative research meticulously attends to the process of the interview that is organized in as unstructured a way as possible. The narrative researcher endeavors to orient the participant to the question of interest in the research and then intervene only to encourage the participant to continue the narration or to clarify what seems confusing to the researcher. Inviting stories, the interviewer asks the participant to detail his or her experiences in rich and specific narration. The interviewer takes an empathic stance toward the interviewees, trying to understand their experience of self and world from their point of view. Elliott Mishler, however, points out that no matter how much the interviewer or researcher attempts to put aside his or her own biases or associations to the interview content, the researcher has impact on what is told and this must be acknowledged and reflected on.

Because such interviews usually elicit highly personal material, confidentiality and respect for the interviewee must be assured. The ethics of the interview are carefully considered in advance, during the interview itself and in preparation of the research report.

Narrative research questions tend to focus on individual, developmental, and social processes that reflect how experience is constructed both internally and externally. Addressing questions that cannot be answered definitively, narrative research embraces multiple interpretations rather than aiming to develop a single truth. Rooted in a postmodern epistemology, narrative approaches to research respect the relativity of knowing—the meanings of the participant filtered through the mind of the researcher with all its assumptions and a priori meanings. Knowledge is presumed to be constructed rather than discovered and is assumed to be localized, perspectival, and occurring within intersubjective relationships to both participants and readers. “Method” then becomes not a set of procedures and techniques but ways of thinking about

inquiry, modes of exploring questions, and creative approaches to offering one's constructed findings to the scholarly community. All communication is through language that is understood to be always ambiguous and open to interpretation. Thus, the analytic framework of narrative research is in hermeneutics, which is the science of imprecise and always shifting meanings.

Analysis

The analysis of narrative research texts is primarily aimed at inductively understanding the meanings of the participant and organizing them at some more conceptual level of understanding. This might involve a close reading of an individual's interview texts, which includes coding for particular themes or extracting significant passages for discussion in the report. The researcher looks inductively for patterns, and the kinds of patterns recognized might reflect the researcher's prior knowledge about the phenomena. The process of analysis is one of piecing together data, making the invisible apparent, deciding what is significant and what is insignificant, and linking seemingly unrelated facets of experience together. Analysis is a creative process of organizing data so the analytic scheme will emerge. Texts are read multiple times in what Friedrich Schleiermacher termed a "hermeneutic circle," a process in which the whole illuminates the parts that in turn offers a fuller and more complex picture of the whole, which then leads to a better understanding of the parts, and so on.

Narrative researchers focus first on the voices *within* each narrative, attending to the layering of voices (subject positions) and their interaction, as well as the continuities, ambiguities, and disjunctions expressed. The researcher pays attention to both the content of the narration ("the told") and the structure of the narration ("the telling"). Narrative analysts might also pay attention to what is unsaid or unsayable by looking at the structure of the narrative discourse and markers of omissions. After each participant's story is understood as well as possible, cross-case analysis might be performed to discover patterns across individual narrative interview texts or to explore what might create differences between people in their narrated experiences.

There are many approaches to analyses, with some researchers focusing on meanings through content and others searching through deconstructing the use and structure of language as another set of markers to meanings. In some cases, researchers aim to depict the layers of experience detailed in the narratives, preserving the point of view, or voice, of the interviewee. At other times, researchers might try to go beyond what is

said and regard the narrated text as a form of disguise; this is especially true when what is sought are unconscious processes or culturally determined aspects of experience that are embedded rather than conscious.

The linguistic emphasis in some branches of narrative inquiry considers the ways in which language organizes both thought and experience. Other researchers recognize the shaping function of language but treat language as transparent as they focus more on the content of meanings that might be created out of life events.

The purpose of narrative research is to produce a deep understanding of dynamic processes. No effort is made to generalize about populations. Thus, statistics, which aims to represent populations and the distribution of variables within them, have little or no place in narrative research. Rather, knowledge is viewed to be localized in the analysis of the particular people studied, and generalization about processes that might apply to other populations is left to the reader. That is, in a report about the challenges of immigration in a particular population, the reader might find details of the interactive processes that might illuminate the struggles of another population in a different locale—or even people confronting other life transitions.

Narrative research avoids having a predetermined theory about the person that the interview or the life-story is expected to support. Although no one is entirely free of preconceived ideas and expectations, narrative researchers try to come to their narrators as listeners open to the surprising variation in their social world and private lives. Although narrative researchers try to be as knowledgeable as possible about the themes that they are studying to be maximally sensitive to nuances of meaning, they are on guard against inflicting meaning in the service of their own ends.

Products

Reports of narrative research privilege the words of the participants, in what Clifford Geertz calls "thick description," and present both some of the raw data of the text as well as the analysis. Offering as evidence the contextualized words of the narrator lends credence to the analysis suggested by the researcher. The language of the research report is often near to experience as lived rather than as obscured by scientific jargon. Even Sigmund Freud struggled with the problem of making the study of experience scientific, commenting in 1893 that the nature of the subject was responsible for his works reading more like short stories than customary scientific reports. The aim of a narrative research report is to offer interpretation in a form that is faithful to the phenomena. In place of formneutral

“objectivized” language, many narrative researchers concern themselves with the poetics of their reports and strive to embody the phenomena in the language they use to convey their meanings. Narrative researchers stay respectful of their participants and reflect on how they are representing “the other” in the published report.

Some recent narrative research has concerned such topics as how people experience immigration, illness, identity, divorce, recovery from addictions, belief systems, and many other aspects of human experience. Any life experiences that people can narrate or represent become fertile ground for narrative research questions. The unity of a life resides in a construction of its narrative, a form in which hopes, dreams, despairs, doubts, plans, and emotions are all phrased.

Although narrative research is generally concerned with individuals’ experience, some narrative researchers also consider narratives that particular collectives (societies, groups, or organizations) tell about themselves, their histories, their dominant mythologies, and their aspirations. Just as personal narratives create personal identity, group narratives serve to bond a community and distinguish it from other collectives.

A good narrative research report will detail a holistic overview of the phenomena under study, capturing data from the inside of the actors with a view to understanding and conceptualizing their meaning making in the contexts within which they live. Narrative researchers recognize that many interpretations of their observations are possible and they argue their interpretive framework through careful description of what they have observed.

Narrative researchers also recognize that they themselves are narrators as they present their organization and interpretation of their data. They endeavor to make their work as interpreters transparent, writing about their own interactions with their participants and their data and remaining mindful of their own social location and personal predilections. This reflexive view of researcher as narrator opens questions about the representation of the other and the nature of interpretive authority, and these are addressed rather than elided.

Advantages and Disadvantages

A major appeal of narrative research is the opportunity to be exploratory and make discoveries free of the regimentation of prefabricated hypotheses, contrived variables, control groups, and statistics. Narrative research can be used to challenge conceptual hegemony in the social sciences or to extend the explanatory power of abstract theoretical ideas. Some of the most

paradigm-defining conceptual revolutions in the study of human experience have come from narrative research—Sigmund Freud, Erik Erikson, and Carol Gilligan being the most prominent examples. New narrative researchers, however, struggle with the vaguely defined procedures on which this research depends and with the fact that interesting results cannot be guaranteed in advance. Narrative research is also labor intensive, particularly in the analysis phase, where text must be read and reread as insights and interpretations develop.

Narrative research is not generalizable to populations but rather highlights the particularities of experience. Many narrative researchers, however, endeavor to place the individual narratives they present in a broader frame, comparing and contrasting their conclusions with the work of others with related concerns. All people are like all other people, like some other people—and also are unique. Readers of narrative research are invited explicitly to apply what is learned to contexts that are meaningful to them.

Narrative research opens possibilities for social change by giving voice to marginalized groups, representing unusual or traumatic experiences that are not conducive to control group designs, and by investigating the ways in which social life (and attendant oppression) is mediated through metanarratives. Readers, then, are challenged to understand their own or their society’s stories in new ways at both experiential and theoretical levels.

NATIONAL COUNCIL ON MEASUREMENT IN EDUCATION

The National Council on Measurement in Education (NCME) is the sole professional association devoted to the scientific study and improvement of educational measurement. Its origin dates back to the National Association of Teachers of Educational Measurement, which was an organization established in 1938 to address the increased use of educational tests in American society and to guard against potential misuse. In 1942, its name was changed to the National Council on Measurements Used in Education, and in 1960, the name was revised to the National Council on Measurement in Education.

As of 2020, NCME had about 1,800 members working in both the United States and throughout the world. According to the mission statement on its website, it is “a community of measurement scientists and practitioners who work together to advance theory and applications of educational measurement to benefit society.” NCME has five broad goals, which are to:

1. Advance the science and scholarship of educational measurement.
2. Promote knowledge, understanding, and implementation of best practices in educational measurement.
3. Increase and strengthen NCME’s partnerships to improve assessment policy and practice.
4. Create and maintain a vibrant, diverse, and inclusive community of measurement practitioners and researchers.
5. Provide members with a strong professional identity and intellectual home (NCME, 2020).

These goals underscore the NCME’s focus on supporting research on educational tests and testing, development of improved assessments in education, and disseminating information regarding new developments in educational testing and the proper use of tests. To accomplish these goals, NCME hosts an annual conference each year, publishes two highly regarded journals covering research and practice in educational measurement, and partners with other professional organizations to develop and disseminate guidelines and standards for appropriate educational assessment practices and to further the understanding of the strengths and limitations of educational tests. In the following sections, some of the most important activities of NCME are described.

Dissemination Activities

NCME publishes two peer-reviewed journals, both of which have four volumes per year: the *Journal of Educational Measurement* (JEM, first published in 1963) and *Educational Measurement: Issues and Practice* (EM:IP, first published in 1982). JEM publishes original measurement research, reports of novel applications of measurement in an educational context, and reviews of measurement publications. EM:IP focuses on more applied issues, typically less statistical in nature, that are of broad interest to measurement practitioners. The primary purpose of EM:IP is to promote a better understanding of educational measurement and to encourage reasoned debate on current issues of practical importance to educators and the public. Both journals are free for NCME members and are published in both print and online.

In addition to the two journals, NCME also publishes the *Instructional Topics in Educational Measurement Series* (ITEMS), which are instructional units on specific measurement topics of interest to measurement researchers and practitioners. The ITEMS units, which first appeared in 1987, are available for free and can be downloaded from the NCME ITEMS portal, which contains print versions of the instructional units as well as instructional videos and exercises. As of August 2020, there were 45 print-based modules and 17 video-based modules covering a broad range of topics such as how to equate tests, evaluate differential item functioning, set achievement level standards on tests, and develop tests for diverse populations.

NCME also publishes a book series that features edited books on important measurement topics such as using technology in assessment, classroom assessment, accountability testing, and test validation. In addition, NCME has partnered with other organizations in publishing books and other materials designed to promote

fair or improved practices related to educational measurement. The most significant partnership has been with the Joint Committee on Testing Standards, which produced the *Standards for Educational and Psychological Testing* in 2014 as well as the five previous versions of those standards (in 1954, 1966, 1974, 1985, and 1999). The *Standards* define best practices in test development and evaluation.

In addition to publishing journals, instructional modules, and books, NCME has also partnered with other professional organizations to publish material to inform educators or the general public about important measurement issues. For example, in 1990, it partnered with the American Federation of Teachers (AFT) and the National Education Association (NEA) to produce the *Standards for Teacher Competence in the Educational Assessment of Students*. It has also been an active member on the Joint Committee on Testing Practices (JCTP) that produced the *ABCs of Testing*, which is a video and booklet designed to inform parents and other lay audiences about the use of tests in schools and about important characteristics of quality educational assessments.

NCME also worked with JCTP to produce the *Code of Fair Testing Practices*, which describes the responsibilities test developers and test users have for ensuring fair and appropriate testing practices. NCME also publishes a quarterly newsletter, which can also be downloaded for free from its website, and position papers and statements, which are also posted on the website. Examples of position papers include “Student Participation in State Assessment” and “K12 Classroom Testing”; an example of a position statement is “Misconceptions about Group Differences in Average Test Scores.”

Annual Conference

In addition to the aforementioned publications, the NCME’s annual conference is another mechanism with which it helps disseminate new findings and research on educational measurement. The annual conference, typically held in March or April, features three full days of paper sessions, symposia, invited speakers, and poster sessions in which psychometricians and other measurement practitioners can learn and dialog about new developments and issues in educational measurement and research. About 1,200 members attend the conference each year.

Governance Structure

The governance structure of NCME consists of an executive committee made up of the president,

president-elect, and immediate past president) and six other members who together form the Board of Directors. All Board positions are elected positions. There are specific slots on the board that rotate in a 3-year cycle so that the board has at least one representative from a governmental setting, a school district or other local setting, and a testing company. NCME has several volunteer committees that are run by its members. Examples of these committees include the Outreach and Partnership Committee and the Diversity Issues and Testing Committee. It also has seven “special interest groups in educational measurement,” which members can join free of charge.

Joining NCME

NCME is open to all professionals working in educational measurement such as university faculty; test developers; state and federal testing and research directors; professional evaluators; testing specialists in business, industry, education, community programs, and other professions; licensure, certification, and credentialing professionals; graduate students from educational, psychological, and other measurement programs; and others involved in testing issues and practices. Membership includes print and digital subscriptions to both journals, access to the NCME membership database, access to special interest group activities, and discount on conference registration. Graduate student membership is at a 50% reduced rate and is free for the first year. All professionals interested in staying current with respect to new developments and research related to measurement in education, psychology, and the professions are encouraged to become members.

NATURAL EXPERIMENTS

Natural experiments are designs that occur in nature and permit a test of an otherwise untestable hypothesis and thereby provide leverage to disentangle variables or processes that would otherwise be inherently confounded. Experiments in nature do not, by definition, have the sort of leverage that traditional experiments have because they were not manufactured to precise methodological detail; they are fortuitous. They do, however, have distinct advantages over observational studies and might, in some circumstances, address questions that randomized controlled trials could not address. A key feature of natural experiments is that they offer insight into causal processes, which is one reason why they have an established role in developmental science.

Natural experiments represent an important research tool because of the methodological limits of naturalistic and experimental designs and the need to triangulate and confirm findings across multiple research designs. Notwithstanding their own set of practical limitations and threats to generalizability of the results,

natural experiments have the potential to deconfound alternative models and accounts and thereby contribute significantly to developmental science and other areas of research. This entry discusses natural experiments in the context of other research designs and then illustrates how their use in developmental science has provided information about the relationship between early exposure to stress and children's development.

The Scientific Context of Natural Experiments

The value of natural experiments is best appreciated when viewed in the context of other designs. A brief discussion of other designs is therefore illustrative. Observational or naturalistic studies—cross-sectional or longitudinal assessments in which individuals are observed and no experimental influence is brought to bear on them—generally cannot address causal claims. That is because a range of methodological threats, including selection biases and coincidental or spurious associations, undermine causal claims. So, for example, in the developmental and clinical psychology literature, there is considerable interest in understanding the impact of parental mental health—maternal depression is probably the most studied example—on children's physical and mental development. Dozens of studies have addressed this question using a variety of samples and measures. However, almost none of these studies—even large-scale cohort and population studies—are equipped to identify causal mechanisms for several reasons, including (a) genetic transmission is confounded with family processes and other psychosocial risks; (b) maternal depression is virtually always accompanied by other risks that are also reliably linked with children's maladjustment, such as poor parenting and marital conflict; and (c) mate selection for psychiatric disorders means that depressed mothers are more likely to have a partner with a mental illness, which confounds any specific “effect” that investigators might wish to attribute to maternal depression per se. Most of the major risk factors relevant to psychological well-being and public health co-occur; in general terms, risk exposures are not distributed randomly in the population. Indeed, one of the more useful lessons from developmental science has been to demonstrate the ways in which exposures to risk accrue in development.

One response to the problems in selection bias or confounded risk exposure is to address the problem analytically. That is, even if, for example, maternal depression is inherently linked with compromised parenting and family conflict, the “effect” of maternal depression might nevertheless be derived if the

confounded variables (compromised parenting and family conflict) are statistically controlled for. There are some problems with that solution, however. If risk processes are confounded in nature, then statistical controlling for one or the other is not a satisfying solution; interpretations of the maternal depression “effect” will be possible but probably not (ecologically) valid. Sampling design strategies to obtain the same kind of leverage, such as sampling families with depressed mothers only if there is an absence of family conflict, will yield an unrepresentative sample of affected families with minimal generalizability. Case-control designs try to gain some leverage over cohort observational studies by tracking a group or groups of individuals, some of whom have a condition(s) of interest. Differences between groups are inferred to be attributable to the condition(s) of interest because the groups were matched on key factors. That is not always possible and the relevant factors to control for are not always known; as a result, between-group and even within-subject variation in these designs is subject to confounders.

A potential methodological solution is offered by experimental designs. So, for example, testing the maternal depression hypothesis referred to previously might be possible to the extent that some affected mothers are randomly assigned to treatment for depression. That would offer greater purchase on the question of whether maternal depression per se was a causal contributor to children’s adjustment difficulties. Interestingly, intervention studies have shown that there are a great many questions about causal processes that emerge even after a successful trial. For example, cognitive-behavioral treatment might successfully resolve maternal depression and, as a result, children of the treated mothers might show improved outcomes relative to children whose depressed mothers were not treated. It would not necessarily follow, however, that altering maternal depression was the causal mediator affecting child behavior. It might be that children’s behavior improved because the no-longer-depressed mothers could engage as parents in a more effective manner and there was a decrease in inter-parental conflict, or any of several other secondary effects of the depression treatment. In other words, questions about causal mechanisms are not necessarily resolved fully by experimental designs.

Investigators in applied settings are also aware that some contexts are simply not amenable to randomized control. School-based interventions sometimes hit resistance to random assignment because principals, teachers, or parents object to the idea that some children needing intervention might not get the presumed better treatment. Court systems are often nonreceptive

experimental proving grounds. That is, no matter how compelling data from a randomized control trial might be to address a particular question, there are circumstances in which a randomized control trial is extremely impractical or unethical.

Natural experiments are, therefore, particularly valuable where traditional nonexperimental designs might not be scientifically inadequate or where experimental designs may be practical or ethical. And natural experiments are useful scientific tools even where other designs might be judged as capable of testing the hypothesis of interest. That is because of the need for findings to be confirmed not only by multiple studies but also by multiple designs. That is, natural experiments can provide a helpful additional scientific “check” on findings generated from naturalistic or experimental studies. There are many illustrations of the problems in relying on findings from a single design. Researchers are now accustomed to defining an effect or association as robust if it is replicated across samples and measures. Also, a finding should replicate across design. No single research sample and no single research design is satisfactory for testing causal hypotheses or inferring causal mechanisms.

Finally, identifying natural experiments can be an engaging and creative process, and studies based on natural experiments are far less expensive and arduous to investigate—they occur naturally—than those using conventional research designs; they can also be common. Thus, dramatic shifts in income might be exploited to investigate income dynamics and children’s well-being; cohort changes in the rates of specific risks (e.g., divorce) might be used to examine psychosocial accounts for children’s adjustment problems. Hypotheses about genetic and/or psychosocial risk exposure might be addressed using adoption and twin designs, and many studies exploit the arbitrariness of age cut-off for school to contrast exposure with maturation accounts of reading, language, and mathematic ability; the impact of compulsory schooling; and many other practical and conceptual questions.

Like all other forms of research design, natural experiments have their own special set of limitations. But, they can offer both novel and confirmatory findings. Examples of how natural experiments have informed the debate on early risk exposure and children’s development are reviewed below.

Natural Experiments to Examine the Long-Term Effects of Early Risk Exposure

Understanding the degree to which, and by what mechanisms, early exposure to stress has long-term effects is

a primary question for developmental science with far-reaching clinical and policy applications. This area of inquiry has been extensively and experimentally studied in animal models. But animal studies are inadequate for deriving clinical and public health meaning; research in humans is essential. However, sound investigation to inform the debate in humans has been overshadowed by claims that might overplay the evidence, as in the case of extending animal findings to humans willy-nilly. The situation is compounded by the general lack of relevant human studies that have leverage for deriving claims about early experience and exposure *per se*. That is, despite the hundreds of studies that assess children's exposure to early risk, almost none can differentiate the effects of early risk exposure from later risk exposure because the exposure to risk—maltreatment, poverty, and parental mental illness—is continuous rather than precisely timed or specific to the child's early life. Intervention studies have played an important role in this debate, and many studies now show long-term effects of early interventions. In contrast, because developmental timing was not separated from intervention intensity in most cases, these studies do not resolve issues about early experience as such. In other words, conventional research designs have not had much success in tackling major questions about early experience. It is not surprising, then, that natural experiments have played such a central role in this line of investigation.

Several different forms of natural experiments to study the effects of early exposure have been reported. One important line of inquiry is from the Dutch birth cohort exposed to prenatal famine during the Nazi blockade. Alan S. Brown and colleagues found that the rate of adult unipolar and bipolar depression requiring hospitalization was increased among those whose mothers experienced starvation during the second and third trimesters of pregnancy. The ability of the study to contrast rates of disorder among individuals whose mothers were and were not pregnant during the famine allowed unprecedented experimental “control” on timing of exposure. A second feature that makes the study a natural experiment is that it capitalized on a situation that is ethically unacceptable and so impossible to design on purpose.

Another line of study that has informed the early experience debate concerns individuals whose caregiving experience undergoes a radical change—far more radical than any traditional psychological intervention could create. Of course, radical changes in caregiving do not happen ordinarily. A notable exception is those children who are removed from abusive homes and placed into nonabusive or therapeutic settings (e.g., foster care). Studies of children in foster care are,

therefore, significant because this is a population for whom the long-term outcomes are generally poor and because this is context in which natural experiments of altering care are conducted. Clearly, there are inherent complications, but the findings have provided some of the most interesting data in clinical and developmental psychology.

An even more extreme context involves children who experienced gross deprivation via institutional care and were then adopted into low-/normal-risk homes. There are many studies of this sort. One is the English and Romanian Adoptees (ERA) study, which is a long-term follow-up of children who were adopted into England after institutional rearing in Romania; the study also includes an early adopted sample of children in England as a comparison group. A major feature of this particular natural experiment—and what makes it and similar studies of exinstitutionalized children noteworthy—is that there was a remarkable discontinuity in caregiving experience, from the most severe to a normal-risk setting. That feature offers unparallel leverage for testing the hypothesis that it is *early* caregiving risk that has persisting effects on long-term development. The success of the natural experiment design depends on many considerations, including the representativeness of the families who adopted from Romania to the general population of families, for example. A full account of this issue is not within the scope of this entry, but it is clear that the impact of findings from natural experiments needs to be judged in relation to the kinds of sampling and other methodological features.

The findings from studies of exinstitutionalized samples correspond across studies. So, for example, there is little doubt now from long-term follow-up assessments that early caregiving deprivation can have long-term impact on attachment and intellectual development, with a sizable minority of children showing persisting deficits many years after the removal from the institutional setting and despite many years in a resourceful, caring home environment. Findings also show that individual differences in response to early severe deprivation are substantial and just as continuous. Research into the effects of early experience has depended on these natural experiments because conventional research designs were either impractical or unethical.

NATURALISTIC INQUIRY

Naturalistic inquiry is an approach to understanding the social world in which the researcher observes, describes, and interprets the experiences and actions of specific people and groups in societal and cultural context. It is a research tradition that encompasses qualitative research methods originally developed in anthropology and sociology, including participant observation, direct observation, ethnographic methods, case studies, grounded theory, unobtrusive methods, and field research methods. Working in the places where people live and work, naturalistic researchers draw on observations, interviews, and other sources of descriptive data, as well as their own subjective experiences, to create rich, evocative descriptions and interpretations of social phenomena. Naturalistic inquiry designs are valuable for exploratory research,

particularly when relevant theoretical frameworks are not available or when little is known about the people to be investigated. The characteristics, methods, indicators of quality, philosophical foundations, history, disadvantages, and advantages of naturalistic research designs are described below.

Characteristics of Naturalistic Research

Naturalistic inquiry involves the study of a single case, usually a self-identified group or community. Self-identified group members are conscious of boundaries that set them apart from others. When qualitative (naturalistic) researchers select a case for study, they do so because it is of interest in its own right. The aim is not to find a representative case from which to generalize findings to other, similar individuals or groups. It is to develop interpretations and local theories that afford deep insights into the human experience.

Naturalistic inquiry is conducted in the field, within communities, homes, schools, churches, hospitals, public agencies, businesses, and other settings. Naturalistic researchers spend large amounts of time interacting directly with participants. The researcher is the research instrument, engaging in daily activities and conversations with group members to understand their experiences and points of view. Within this tradition, language is considered a key source of insight into socially constructed worlds. Researchers record participants' words and actions in detail with minimal interpretation. Although focused on words, narratives, and discourse, naturalistic researchers learn through all of their senses. They collect data at the following experiential levels: cognitive, social, affective, physical, and political/ideological. This strategy adds depth and texture to the body of data qualitative researchers describe, analyze, and interpret.

Naturalistic researchers study research problems and questions that are initially stated broadly then gradually narrowed during the course of the study. In non-naturalistic, experimental research designs, terms are defined, research hypotheses stated, and procedures for data collection established in advance before the study begins. In contrast, qualitative research designs develop over time as researchers formulate new understandings and refine their research questions. Throughout the research process, naturalistic researchers modify their methodological strategies to obtain the kinds of data required to shed light on more focused or intriguing questions. One goal of naturalistic inquiry is to generate new questions that will lead to improved observations and interpretations, which will in turn foster the formulation of still better questions. The process is circular but ends when the researcher has

created an account that seems to capture and make sense of all the data at hand.

Naturalistic Research Methods

General Process

When naturalistic researchers conduct field research, they typically go through the following common sequence of steps:

1. Gaining access to and entering the field site
2. Gathering data
3. Ensuring accuracy and trustworthiness (verifying and cross-checking findings)
4. Analyzing data (begins almost immediately and continues throughout the study)
5. Formulating interpretations (also an ongoing process)
6. Writing up findings
7. Member checking (sharing conclusions and conferring with participants)
8. Leaving the field site

Sampling

Naturalistic researchers employ purposive rather than representative or random sampling methods. Participants are selected based on the purpose of the study and the questions under investigation, which are refined as the study proceeds. This strategy might increase the possibility that unusual cases will be identified and included in the study. Purposive sampling supports the development of theories grounded in empirical data tied to specific local settings.

Analyzing and Interpreting Data

The first step in qualitative data analysis involves transforming experiences, conversations, and observations into text (data). When naturalistic researchers analyze data, they review field notes, interview transcripts, journals, summaries, and other documents looking for repeated patterns (words, phrases, actions, or events) that are salient by virtue of their frequency. In some instances, the researcher might use descriptive statistics to identify and represent these patterns.

Interpretation refers to making sense of what these patterns or themes might mean, developing explanations, and making connections between the data and relevant studies or theoretical frameworks. For example, reasoning by analogy, researchers might note

parallels between athletic events and anthropological descriptions of ritual processes. Naturalistic researchers draw on their own understanding of social, psychological, and economic theory as they formulate accounts of their findings. They work inductively, from the ground up, and eventually develop location-specific theories or accounts based on analysis of primary data.

As a by-product of this process, new research questions emerge. Whereas traditional researchers establish hypotheses prior to the start of their studies, qualitative researchers formulate broad research questions or problem statements at the start, then reformulate or develop new questions as the study proceeds. The terms *grounded theory*, *inductive analysis*, and *content analysis*, although not synonymous, refer to this process of making sense of and interpreting data.

Evaluating Quality

The standards used to evaluate the adequacy of traditional, quantitative studies should not be used to assess naturalistic research projects. Quantitative and qualitative researchers work within distinct traditions that rest on different philosophical assumptions, employ different methods, and produce different products. Qualitative researchers argue among themselves about how best to evaluate naturalistic inquiry projects, and there is little consensus on whether it is possible or appropriate to establish common standards by which such studies might be judged. However, many characteristics are widely considered to be indicators of merit in the design of naturalistic inquiry projects.

Immersion

Good qualitative studies are time consuming. Researchers must become well acquainted with the field site and its inhabitants as well as the wider context within which the site is located. They also immerse themselves in the data analysis process, through which they read, review, and summarize their data.

Transparency and Rigor

When writing up qualitative research projects, researchers must put themselves in the text, describing how the work was conducted, how they interacted with participants, how and why they decided to proceed as they did, and noting how participants might have been affected by these interactions. Whether the focus is on interview transcripts, visual materials, or field research notes, the analytical process requires meticulous attention to detail and an inductive, bottom-up process of reasoning that should be made clear to the reader.

Reflexivity

Naturalistic inquirers do not seek to attain objectivity, but they must find ways to articulate and manage their subjective experiences. Evidence of one or more forms of reflexivity is expected in naturalistic inquiry projects. Positional reflexivity calls on researchers to attend to their personal experiences—past and present—and describe how their own personal characteristics (power, gender, ethnicity, and other intangibles) played a part in their interactions with and understandings of participants. Textual reflexivity involves skeptical, self-critical consideration of how authors (and the professional communities in which they work) employ language to construct their representations of the social world. A third form of reflexivity examines how participants and the researchers who study them create social order through practical, goal-oriented actions and discourse.

Comprehensiveness and Scope

The cultural anthropologist Clifford Geertz used the term *thick description* to convey the level of rich detail typical of qualitative, ethnographic descriptions. When writing qualitative research reports, researchers place the study site and findings as a whole within societal and cultural contexts. Effective reports also incorporate multiple perspectives, including perspectives of participants from all walks of life (for example) within a single community or organization.

Accuracy

Researchers are expected to describe the steps taken to verify findings and interpretations. Strategies for verification include triangulation (using and confirming congruence among multiple sources of information), member checking (negotiating conclusions with participants), and auditing (critical review of the research design, processes, and conclusions by an expert).

Claims and Warrants

In well-designed studies, naturalistic researchers ensure that their conclusions are supported by empirical evidence. Furthermore, they recognize that their conclusions follow logically from the design of the study, including the review of pertinent literature, data collection, analysis, interpretation, and the researcher's inferential process.

Attention to Ethics

Researchers should describe the steps taken to protect participants from harm and discuss any ethical issues that arose during the course of the study.

Fair Return

Naturalistic inquiry projects are time consuming not only for researchers but also for participants, who teach researchers about their ways of life and share their perspectives as interviewees. Researchers should describe what steps they took to compensate or provide fair return to participants for their help. Research leads to concrete benefits for researchers (degree completion or career advancement). Researchers must examine what benefits participants will gain as a result of the work and design their studies to ensure reciprocity (balanced rewards).

Coherence

Good studies call for well-written and compelling research reports. Standards for writing are genre specific. Postmodern authors defy tradition through experimentation and deliberate violations of writing conventions. For example, some authors avoid writing in clear, straightforward prose to express more accurately the complexities inherent in the social world and within the representational process.

Veracity

A good qualitative report brings the setting and its residents to life. Readers who have worked or lived in similar settings find the report credible because it reflects aspects of their own experiences.

Illumination

Good naturalistic studies go beyond mere description to offer new insights into social and psychological phenomena. Readers should learn something new and important about the social world and the people studied, and they might also gain a deeper understanding of their own ways of life.

Philosophical Foundations

Traditional scientific methods rest on philosophical assumptions associated with logical positivism. When working within this framework, researchers formulate hypotheses that are drawn from established theoretical frameworks, define variables by stipulating the

processes used to measure them, collect data to test their hypotheses, and report their findings objectively. Objectivity is attained through separation of the researcher from participants and by dispassionate analysis and interpretation of results. In contrast, naturalistic researchers tap into their own subjective experiences as a source of data, seeking experiences that will afford them an intuitive understanding of social phenomena through empathy and subjectivity. Qualitative researchers use their subjective experiences as a source of data to be carefully described, analyzed, and shared with those who read their research reports.

For the naturalistic inquirer, objectivity and detachment are neither possible nor desirable. Human experiences are invariably influenced by the methods used to study them. The process of being studied affects all humans who become subjects of scientific attention. The presence of an observer affects those observed. Furthermore, the observer is changed through engaging with and observing the other. Objectivity is always a matter of degree.

Qualitative researchers are typically far less concerned about objectivity as this term is understood within traditional research approaches than with intersubjectivity. Intersubjectivity is the process by which humans share common experiences and subscribe to shared understandings of reality. Naturalistic researchers seek involvement and engagement rather than detachment and distance. They believe that humans are not rational beings and cannot be understood adequately through objective, disembodied analysis. Authors critically examine how their theoretical assumptions, personal histories, and methodological decisions might have influenced findings and interpretations (positional reflexivity). In a related vein, naturalistic researchers do not believe that political neutrality is possible or helpful. Within some qualitative research traditions, researchers collaborate with participants to bring about community-based political and economic change (social justice).

Qualitative researchers reject determinism, the idea that human behaviors are lawful and can be predicted. Traditional scientists try to discover relationships among variables that remain consistent across individuals beyond the experimental setting. Naturalistic inquiry rests on the belief that studying humans requires different methods than those used to study the material world. Advocates emphasize that no shared, universal reality remains constant over time and across cultural groups. The phenomena of most interest to naturalistic researchers are socially constructed, constantly changing, and multiple. Naturalistic researchers hold that all human phenomena occur within

particular contexts and cannot be interpreted or understood apart from these contexts.

History

The principles that guide naturalistic research methods were developed in biology, anthropology, and sociology. Biologist Charles Darwin developed the natural history method, which employs detailed observation of the natural world directed by specific research questions and theory building based on analysis of patterns in the data, followed by confirmation (testing) with additional observations in the field. Qualitative researchers use similar strategies, which transform experiential, qualitative information gathered in the field into data amenable to systematic investigation, analysis, and theory development.

Ancient adventurers, writers, and missionaries wrote the first naturalistic accounts, describing the exotic people they encountered on their travels. During the early decades of the 20th century, cultural anthropologists and sociologists pioneered the use of ethnographic research methods for the scientific study of social phenomena. Ethnography is both a naturalistic research methodology and a written report that describes field study findings. Although there are many different ethnographic genres, all of them employ direct observation of naturally occurring events in the field. Early in the 20th century, University of Chicago sociologists used ethnographic methods to study urban life, producing pioneering studies of immigrants, crime, work, youth, and group relations. Sociologist Herbert Blumer, drawing on George Herbert Mead, William I. Thomas, and John Dewey, developed a rationale for the naturalistic study of the social world. In the 1970s, social scientists articulated ideas and theoretical issues pertinent to naturalistic inquiry. Interest in qualitative research methods grew. In the mid-1980s, Yvonne Lincoln and Egon Guba published *Naturalistic Inquiry*, which provided a detailed critique of positivism and examined implications for social research. Highlighting the features that set qualitative research apart from other methods, these authors also translated key concepts across what they thought were profoundly different paradigms (disciplinary worldviews). In recent years, qualitative researchers considered the implications of critical, feminist, postmodern, and poststructural theories for their enterprise. The recognition or rediscovery that researchers create the phenomena they study and that language plays an important part in this process has inspired methodological innovations and lively discussions. The discourse on naturalistic inquiry remains complex and ever changing. New issues and

controversies emerge every year, reflecting philosophical debates within and across many academic fields.

Methodological Disadvantages and Advantages

Disadvantages

Many areas are not suited to naturalistic investigation. Naturalistic research designs cannot uncover cause and effect relationships and they cannot help researchers evaluate the effectiveness of specific medical treatments, school curricula, or parenting styles. They do not allow researchers to measure particular attributes (motivation, reading ability, or test anxiety) or to predict the outcomes of interventions with any degree of precision. Qualitative research permits only claims about the specific case under study. Generalizations beyond the research site are not appropriate. Furthermore, naturalistic researchers cannot set up logical conditions whereby they can demonstrate their own assumptions to be false.

Naturalistic inquiry is time consuming and difficult. Qualitative methods might seem to be easier to use than traditional experimental and survey methods because they do not require mastery of technical statistical and analytical methods. However, naturalistic inquiry is one of the most challenging research approaches to learn and employ. Qualitative researchers tailor methods to suit each project, revising data-collection strategies as questions and research foci emerge. Naturalistic researchers must have a high tolerance for uncertainty and the ability to work independently for extended periods of time, and these researchers must also be able to think creatively under pressure.

Advantages

Once controversial, naturalistic research methods are now used in social psychology, developmental psychology, qualitative sociology, and anthropology. Researchers in professional schools (education, nursing, health sciences, law, social work, and counseling) and applied fields (regional planning, library science, program evaluation, information science, and sports administration) employ naturalistic strategies to investigate social phenomena. Naturalistic approaches are well suited to the study of groups about which little is known. They are also holistic and comprehensive. Qualitative researchers try to tell the whole story, in context. A well-written report has some of the same characteristics as a good novel, bringing the lives of participants to life. Naturalistic methods help

researchers understand how people view the world, what they value, and how these values and cognitive schemas are reflected in practices and social structures. Through the study of groups unlike their own, researchers learn that many different ways are available to raise children, teach, heal, maintain social order, and initiate change. Readers learn about the extraordinary variety of designs for living and adaptive strategies humans have created, thus broadening awareness of possibilities beyond conventional ways of life. Thus, naturalistic inquiry can provide insights that deepen our understanding of the human experience and generate new theoretical insights. For researchers, the process of performing qualitative research extends and intensifies the senses and provides interesting and gratifying experiences as relationships are formed with the participants from whom and with whom one learns.

NATURALISTIC OBSERVATION

Naturalistic observation is a nonexperimental, primarily qualitative research method in which organisms are studied in their natural settings. Behaviors or other phenomena of interest are observed and recorded by the researcher, whose presence might be either known

or unknown to the subjects. This approach falls within the broader category of field study, or research conducted outside the laboratory or institution of learning. No manipulation of the environment is involved in naturalistic observation, as the activities of interest are those manifested in everyday situations. This method is frequently employed during the initial stage of a research project, both for its wealth of descriptive value and as a foundation for hypotheses that might later be tested experimentally.

Zoologists, naturalists, and ethologists have long relied on naturalistic observation for a comprehensive picture of the variables coexisting with specific animal behaviors. Charles Darwin's 5-year voyage aboard the H.M.S. *Beagle*, which is an expedition that culminated in his theory of evolution and the publication of his book *On the Origin of Species* in 1859, is a paradigm of research based on this method. Studies of interactions within the social structures of primates by both Dian Fossey and Jane Goodall relied on observation in the subjects' native habitats. Konrad Lorenz, Niko Tinbergen, and Karl von Frisch advanced the understanding of communication among animal species through naturalistic observation, introducing such terminology as imprinting, fixed action pattern, sign stimulus, and releaser to the scientific lexicon. All the investigations mentioned here were notable for their strong ecological validity, as they were conducted within a context reflective of the normal life experiences of the subjects. It is highly doubtful that the same richness of content could have been obtained in an artificial environment devoid of concurrent factors that would have normally accompanied the observed behaviors.

The instances in which naturalistic observation also yields valuable insight to psychologists, social scientists, anthropologists, ethnographers, and behavioral scientists in the study of human behavior are many. For example, social deficits symptomatic of certain psychological or developmental disorders (such as autism, childhood aggression, or anxiety) might be evidenced more clearly in a typical context than under simulated conditions. The dynamics within a marital or family relationship likewise tend to be most perceptible when the participants interact as they would under everyday circumstances. In the study of broader cultural phenomena, a researcher might collect data by living among the population of interest and witnessing activities that could only be observed in a real-life situation after earning their trust and their acceptance as an "insider."

This entry begins with the historic origins of naturalistic observation. Next, the four types of naturalistic observation are described and naturalistic observation and experimental methods are compared. Last, this

entry briefly discusses the future direction of naturalistic observation.

Historic Origins

The field of qualitative research gained prominence in the United States during the early 20th century. Its emergence as a recognized method of scientific investigation was taking place simultaneously in Europe, although the literature generated by many of these proponents was not available in the Western Hemisphere until after World War II. At the University of Chicago, such eminent researchers as Robert Park, John Dewey, Margaret Mead, and Charles Cooley contributed greatly to the development of participant observation methodology in the 1920s and 1930s. The approach became widely adopted among anthropologists during these same two decades. In Mead's 1928 study "Coming of Age in Samoa," data were collected while she resided among the inhabitants of a small Samoan village, making possible her groundbreaking revelations on the lives of girls and women in this island society.

Over the years, naturalistic observation became a widely used technique throughout the many scientific disciplines concerned with human behavior. Among its best-known practitioners was Jean Piaget, who based his theory of cognitive development on observations of his own children throughout the various stages of their maturation; in addition, he would watch other children at play, listening to and recording their interactions. Jeremy Tunstall conducted a study of fishermen in the English seaport of Hull by living among them and working beside them, a sojourn that led to the publication of his book *Fishermen: The Sociology of an Extreme Occupation* in 1962. Stanley Milgram employed naturalistic observation in an investigation on the phenomenon of "familiar strangers" (people who encountered but never spoke to one another) among city dwellers, watching railway commuters day after day as they waited to board the train to their workplaces in New York City. At his Family Research Laboratory in Seattle, Washington, John Gottman has used audiovisual monitoring as a component of his marriage counseling program since 1986. Couples stay overnight in a fabricated apartment at the laboratory, and both qualitative data (such as verbal interactions, proxemics, and kinesics) and quantitative data (such as heart rate, pulse amplitude, and skin conductivity) are collected. In his book *The Seven Principles for Making Marriage Work*, Gottman reported that the evidence gathered during this phase of therapy enabled him to predict whether a marriage would fail or succeed with 91% accuracy.

Types of Naturalistic Observation

Naturalistic observation might be divided into four distinct categories. Each differs from the others in terms of basic definitions, distinguishing features, strengths and limitations, and appropriateness for specific research designs.

Overt Participant Observation

In this study design, subjects are aware that they are being observed and are apprised of the research purpose prior to data collection. The investigator participates in the activities of the subjects being studied and might do this by frequenting certain social venues, taking part in the affairs of an organization, or living as a member of a community. For example, a researcher might travel with a tour group to observe how people cope with the inability to communicate in a country where an unfamiliar language is spoken.

The nature of this study design obviates several ethical concerns, as no deception is involved. However, reactivity to the presence of the observer might compromise internal validity. The Hawthorne effect, in which behavioral and performance-related changes (usually positive) occur as a result of the experimenter's attention, is one form of reactivity. Other problems might ensue if subjects change their behaviors after learning the purpose of the experiment. These artifacts might include social desirability bias, attempts to confirm any hypotheses stated or suggested by the investigator, or noncooperation with the aim of disconfirming the investigator's hypotheses. Reluctant subjects might also anticipate the presence of the investigator and might take measures to avoid being observed.

Covert Participant Observation

In many circumstances, disclosure of the investigator's purpose would jeopardize the successful gathering of data. In such cases, covert participant observation allows direct involvement in the subjects' activities without revealing that a study is being conducted. The observer might join or pretend to join an organization; assume the role of a student, instructor, or supervisor; or otherwise mingle unobtrusively with subjects to gain access to relevant information. Observation via the internet might involve signing up for a website membership using a fictitious identity and rationale for interest in participation. A study in which investigators pretend to be cult members to gather information on the dynamics of indoctrination is one instance of covert participant observation.

Certain distinct benefits are associated with this approach. As subjects remain oblivious to the presence of the researcher, reactivity to the test situation is eliminated. Frequently, it is easier to win the confidence of subjects if they believe the researcher to be a peer. However, measures taken to maintain secrecy might also restrict the range of observation. Of even greater concern is the potential breach of ethics represented by involving subjects in a study without their informed consent. In all such cases, it is important to consider whether the deception involved is justified by the potential benefits to be reaped. The ethical principles of such professional organizations as the American Psychological Association, American Medical Association, and American Counseling Association stress the overarching goal of promoting the welfare and respecting the dignity of the client or patient. This can be summarized as an aspirational guideline to do no harm. Apart from avoiding physical injury, it is necessary to consider and obviate any aspects of the study design that could do psychological or emotional damage. Even when potentially detrimental effects fail to materialize, the practitioner is responsible for upholding the principle of integrity in his or her professional conduct and for performing research honestly and without misrepresentation. Finally, subjects might eventually learn of their involuntary inclusion in research, and the consequent potential for litigation cannot be taken lightly. The issue of whether to extenuate deception to gain information that might not otherwise be procured merits serious deliberation and is not treated casually in research design.

Overt Nonparticipant Observation

The primary distinction between this method and overt participant observation is the role of the observer, who remains separate from the subjects being studied. Of the two procedures, nonparticipant observation is implemented in research more frequently. Subjects acknowledge the study being conducted and the presence of the investigator, who observes and records data but does not mingle with the subjects. For instance, a researcher might stand at a subway station, watching commuters and surreptitiously noting the frequency of discourteous behaviors during rush hour as opposed to off-peak travel times.

A major advantage of overt nonparticipant observation is the investigator's freedom to use various tools and instruments openly, thus enabling easier and more complete recording of observations. (In contrast, a covert observer might be forced to write hasty notes on pieces of paper to avoid suspicion and to attempt reconstruction of fine details from memory later on.)

Still, artifacts associated with awareness of the investigator's presence might persist, even though observation from a distance might tend to exert less influence on subjects' behavior. In addition, there is virtually no opportunity to question subjects should the researcher wish to obtain subsequent clarification of the meaning attached to an event. The observer might, thus, commit the error of making subjective interpretations based on inconclusive evidence.

Covert Nonparticipant Observation

This procedure involves observation conducted apart from the subjects being studied. As in covert participant observation, the identity of the investigator is not revealed. Data are often secretly recorded and hidden; alternatively, observations might be documented at a later time when the investigator is away from the subjects. Witnessing events by means of electronic devices is also a form of covert nonparticipant observation. For example, the researcher might watch a videotape of children at recess to observe peer aggression.

The covert nonparticipant observer enjoys the advantages of candid subject behavior as well as the availability of apparatus with which to record data immediately. However, as in covert participant observation, measures taken to preserve anonymity might also curtail access to the full range of observations. Remote surveillance might similarly offer only a limited glimpse of the sphere of contextual factors, thereby diminishing the usefulness of the data. Finally, the previously discussed ethical infractions associated with any form of covert observation, as well as the potential legal repercussions, make using this method highly controversial.

Comparing Naturalistic Observation With Experimental Methods

The advantages offered by naturalistic observation are many, whether in conjunction with experimental research or as the primary constituent of a study. First, there is less formal planning than in the experimental method, and also more flexibility is involved in accommodating change throughout the research process. These attributes make for an ideal preliminary procedure, one that might serve to lay the groundwork for a more focused investigation. As mentioned earlier, unexpected observations might generate new hypotheses, thereby contributing to the comprehensiveness of any research based thereon.

By remaining unobtrusive, the observer has access to behaviors that are more characteristic, more

spontaneous, and more diverse than those one might witness in a laboratory setting. In many instances, such events simply cannot be examined in a laboratory setting. To learn about the natural behavior of a wild animal species, the workplace dynamics of a corporate entity, or the culturally prescribed roles within an isolated society, the investigator must conduct observations in the subjects' day-to-day environment. This requirement ensures a greater degree of ecological validity than one could expect to achieve in a simulated environment. However, there are no implications for increased external validity. As subjects are observed by happenstance, not selected according to a sampling procedure, representativeness cannot be guaranteed. Any conclusions drawn must necessarily be limited to the sample studied and cannot generalize to the population.

There are other drawbacks to naturalistic observation vis-à-vis experimental methods. One of these is the inability to control the environment in which subjects are being observed. Consequently, the experimenter can derive descriptive data from observation but cannot establish cause-and-effect relationships. Not only does this preclude explanation of why behaviors occur, but also it limits the prediction of behaviors. Additionally, the natural conditions observed are unique in all instances, thus rendering replication unfeasible.

The potential for experimenter bias is also significant. Whereas the number of times a behavior is recorded and the duration of the episode are both unambiguous measures, the naturalistic observer lacks a clear-cut system for measuring the extent or magnitude of a behavior. Perception of events might thus be influenced by any number of factors, including personal worldview. An especially problematic situation might arise when the observer is informed of the hypothesis and of the conditions under investigation, as this might lead to seeking confirmatory evidence. Another possible error is that of the observer recording data in an interpretative rather than a descriptive manner, which can result in an *ex post facto* conclusion of causality. The researcher's involvement with the group in participant observation might constitute an additional source of bias. Objectivity can suffer because of group influence, and data might also be colored by a strong positive or negative impression of the subjects.

Experimental approaches to research differ from naturalistic observation on a number of salient points. One primary advantage of the true experiment is that a hypothesis can be tested and a cause-and-effect relationship can be demonstrated. The independent variable of interest is systematically manipulated, and the

effects of this manipulation on the dependent variable are observed. Because the researcher controls the environment in which the study is conducted, it is thus possible to eliminate confounding variables. Besides enabling attribution of causality, this design also provides evidence of why a behavior occurs and allows prediction of when and under what conditions the behavior is likely to occur again. Unlike naturalistic observation, an experimental study can possess internal and external validity, although the controls inherent in this approach can diminish ecological validity, as it might be difficult to eliminate extraneous variables while maintaining some semblance of a real-world setting.

An additional benefit of experimental research is the relative stability of the environment in which the researcher conducts the study. In contrast, participant observation might entail a high degree of stress and personal risk when working with certain groups (such as gang members or prison inmates). This method also demands investment of considerable time and expense, and the setting might not be conducive to management of other responsibilities.

Although experimental design is regarded as a more conclusive method than naturalistic observation and is more widely used in science, it is not suitable for all research. Ethical and legal guidelines might forbid an experimental treatment if it is judged capable of harming subjects. For example, in studying the progression of a viral infection such as HIV, the investigator is prohibited from causing subjects to contract the illness and must instead recruit those who have already tested positive for the virus. Similarly, only preexisting psychiatric conditions (such as posttraumatic stress disorder) are studied, as subjects cannot be exposed to manipulations that could cause psychological or emotional trauma. Certain factors might be difficult or impossible to measure, as is the case with various cognitive processes.

The researcher's choice of method can either contribute to or, conversely, erode scientific rigor. If a convenience sample is used, if there are too few subjects in the sample, if randomization is flawed, or if the sample is otherwise not representative of the population from which it is selected, then the study will not yield generalizable results. The use of an instrument with insufficient reliability and validity might similarly undermine the experimental design. Nonetheless, bias and human error are universal in all areas of research. Self-awareness, critical thinking, and meticulous research methods can do much to minimize their ill effects.

Future Directions

Robert Elliott and his colleagues proposed new guidelines for the publication of qualitative research studies in 1999, with the goal of encouraging legitimization, quality control, and subsequent development of this approach. Their exposition of both the traditional value and the current evolution of qualitative research was a compelling argument in support of its function not only as a precursor to experimental investigations but also as a method that addressed a different category of questions and therefore merited recognition in its own right. Given the ongoing presence of nonexperimental approaches in college and university curricula and in the current literature, it is likely that naturalistic observation will continue to play a vital role in scientific research.

NEGATIVE HYPERGEOMETRIC DISTRIBUTION

Negative hypergeometric distribution, also known as the *inverse hypergeometric* or *hypergeometric waiting-time distribution*, is of interest in applications of inverse sampling without replacement from a finite population where a binary observation is made on each sampling unit. For example, imagine that a credit card company estimates that 18 of its 583 platinum card holders have gained their wealth illegally. A banking regulator is to perform an audit. “How many randomly selected platinum card holders will they have to investigate before finding a criminal?” It should be used in any situation where there is hypergeometric sampling and one is asking the question, “How many failures will I observe before I get s successes?” or alternatively “How many samples do I need to have s successes?” Sampling is performed by randomly choosing units sequentially one at a time until a specified number of one of the two types is selected for the sample. The probability distribution function for a random variable that has a negative hypergeometric distribution was described by Samuel Wilks (1963), discussed by Norman L. Johnson and Samuel Kotz (1969), and developed by William C. Guenther (1975). Daniel Zelterman (2005) presented some variations of the negative hypergeometric distribution.

Discrete distributions, such as the binomial, geometric, hypergeometric, and negative binomial, are discussed in most calculus-based introductory statistic books. But the negative hypergeometric has not appeared often in such books or in literature. Generally, many people have used all of these discrete distributions in a probability unit, often without even realizing it. That is, they have calculated probabilities from scratch using the ideas of permutations and combinations. For example, a person may be asked to find the probability when a fair coin is tossed six times that exactly two are heads. Even though this example follows a binomial distribution, the person learns how to construct this probability prior to ever hearing the name of that distribution. This entry aims to distinguish rather than confuse binomial, hypergeometric, negative binomial, and negative hypergeometric distributions and to understand the general form of the probability mass functions, the expected value and variance of the negative hypergeometric distribution.

Discrete distributions can be divided into the two categories as to sampling: from either an infinite- or a

finite-sized population. Finite-sized populations are assumed to be sampled without replacement. In a finite population, the probability of future events depends on the composition of individuals already sampled. In infinite populations, the distribution of future events is independent of those of the past.

The binomial distribution describes the number of successes when a predetermined number of items are independently sampled from an infinitely large Bernoulli population. The hypergeometric distribution is the corresponding model when the population has a finite size. The negative binomial and negative hypergeometric distributions describe the number of trials necessary in order to obtain a specified number of “successes.” It describes properties of a discrete-valued random variable Y whose support is taken to be $0, 1, \dots$ or a finite subset of these nonnegative integers.

The simplest example of a random variable is the Bernoulli random variable for which

$$\Pr[Y = 1] = p \text{ and } \Pr[Y = 0] = 1 - p \quad (1)$$

for probability parameter p satisfying $0 \leq p \leq 1$. The values of $Y = 1$ and $Y = 0$ are often referred to as *successes* and *failures*, respectively.

The binomial distribution is the sum of n independent and identically distributed (iid) Bernoulli p random variables. The valid parameter values are $0 \leq p \leq 1$, $n = 1, 2, \dots$. The parameter n is often referred to as the *sample size* of the binomial distribution. The probability that the sum of n iid Bernoulli random variables is equal to y is defined

$$\Pr[Y = y] = \binom{n}{y} p^y (1 - p)^{n-y} \quad (2)$$

for $y = 0, 1, \dots, n$ and zero otherwise.

Suppose we continue to sample Bernoulli distributed events with probability parameter p until we obtain c successes. The value of $c = 1, 2, \dots$ is determined before sampling begins. The sampling process ends with the observation of the c th success. The negative binomial distribution describes the number of failures observed before the c th success has been achieved. The number of failures Y until the c th success follows the negative binomial distribution with mass function

$$\Pr[Y = y] = \binom{c+y-1}{c-1} p^c (1-p)^y \quad (3)$$

for $y = 0, 1, \dots$

Consider an urn containing N balls. Of these, suppose m are of the “successful” color and the remaining $N - m$ are of the “unsuccessful” type. We reach into the urn and draw out a sample of size n balls. The hypergeometric distribution describes the number of successful colored balls in our sample of size n .

The probability mass function of the hypergeometric distribution is

$$\Pr[Y = y] = \frac{\binom{m}{y} \binom{N-m}{n-y}}{\binom{N}{n}} \quad (4)$$

y out of the m successful types are sampled and $n - y$ out of the $N - m$ unsuccessful types are sampled. The denominator considers all possible ways in which samples of size n can be drawn out of the total N .

The negative hypergeometric distribution is the distribution of the number of unsuccessful draws, one at a time, from an urn with two different colored balls until a specified number of successful draws have been obtained. If m out of N balls are of the successful type, then the number of unsuccessful draws Y observed before c of the successful types are obtained is

$$\Pr[Y = y] = \frac{\binom{c+y-1}{c-1} \binom{N-c-y}{m-c}}{\binom{N}{m}} \quad (5)$$

with parameter satisfying $1 \leq c \leq m < N$ and range $Y = 0, 1, \dots, N - m$.

The expected value of Y

$$E[Y = y] = mc / (N - m + 1) \quad (6)$$

The variance of the negative hypergeometric distribution is

$$\text{Var}[Y = y] = mc(N+1)(N-m-c+1) / (N-m+1)^2 (N-m+2) \quad (7)$$

The comparison of four discrete sampling distributions is given in Table 1. The binomial, negative binomial distributions all assume that they are independently

Table 1 Comparison of Four Discrete Sampling Distributions

Sampling	Infinite population/ with replacement	Finite population without replacement
Predetermined number of items	Binomial	Hypergeometric
Until c successes	Negative binomial	Negative hypergeometric

sampling from an infinitely large family population or with replacement. The hypergeometric and negative hypergeometric distributions are the methodology for sampling from a finite population without replacement.

NESTED FACTOR DESIGN

In nested factor design, two or more factors are not completely crossed; that is, the design does not include each possible combination of the levels of the factors. Rather, one or more factors are nested within the levels of another factor. For example, in a design in which a factor (factor B) has four levels and is nested within the two levels of a second factor (factor A), levels 1 and 2 of factor B would only occur in combination with level 1 of factor A, and levels 3 and 4 of factor B would only be combined with level 2 of factor A. In other words, in a nested factor design, there are cells that are empty. In the described design, for example, no observations are made for the combination of level 1 of factor A and level 3 of factor B. When a factor B is nested under a factor A, this is denoted as B(A). In more complex designs, a factor can also be nested under combinations of other factors. A common example in which factors are nested is within treatments—for example, the evaluation of psychological treatments when therapists or treatment centers provide one treatment to more than one participant. Because each therapist or treatment center provides only one treatment, the provider or treatment center factor is nested under only one level of the treatment factor. Nested factor designs are also common in educational research in which classrooms

of students are nested within classroom interventions. For example, researchers commonly assign whole classrooms to different levels of a classroom-intervention factor. Thus, each classroom, or cluster, is assigned to only one level of the intervention factor and is said to be nested under this factor. Ignoring a nested factor in the evaluation of a design can lead to consequences that are detrimental to the validity of statistical decisions. The main reason for this is that the observations within the levels of a nested factor are likely to not be independent of each other but related. The magnitude of this relationship can be expressed by a so-called intraclass correlation coefficient ρ_1 .

The focus of this entry is on the most common nested design: the two-level nested design. This entry discusses whether nested factors are random or fixed effects and the implications of nested designs on statistical power. In addition, the criteria to determine which model to use and the consequences of ignoring nested factors are also examined.

Two-Level Nested Factor Design

The most common nested design involves two factors with a factor B nested within the levels of a second factor A. The linear structural model for this design can be given as follows:

$$Y_{ijk} = \mu + \alpha_j + \beta_{k(j)} + \varepsilon_{ijk}, \quad (1)$$

where Y_{ijk} is the observation for the i th subject ($i = 1, 2, \dots, n$) in the j th level of factor A ($j = 1, 2, \dots, p$) and the k th level of the nested factor B ($k = 1, 2, \dots, q$), μ is the grand mean, α_j is the effect for the j th treatment, $\beta_{k(j)}$ is the effect of the k th provider nested under the j th treatment, and ε_{ijk} is the error of the observation (within cell variance). Note that because factors A and B are not completely crossed, the model does not include an interaction term because it cannot be estimated separately from the error term. More generally speaking, because nested factor designs have not as many cells as completely crossed designs, one cannot perform all tests for main effects and interactions.

The assumptions of the nested model are that the effects of the fixed factor A sum up to zero

$$\sum_j \alpha_j = 0, \quad (2)$$

that errors are normally distributed and have an expected value of zero

$$\varepsilon_{ijk} \sim N(0, \sigma_{\varepsilon_{i(jk)}}^2), \text{ and that} \quad (3)$$

$$\varepsilon_{i(jk)}, \alpha_j, \text{ and } \beta_{k(j)} \text{ are pairwise independent.} \quad (4)$$

In the next section, the focus is on nested factor designs with two factors with one of the factors nested under the other. More complex models can be built analogously. For example, the model equation for a design with two crossed factors, A and B, and a third factor nested within factor C is described by the following structural model:

$$Y_{ijkm} = \mu + \alpha_i + \beta_j + \gamma_{k(i)} + (\alpha\beta)_{jk(i)} + \varepsilon_{ijkm}. \quad (5)$$

Nested Factors as Random and Fixed Effects

In experimental and quasi-experimental designs, the factor under which the second factor is nested is almost always conceptualized as a fixed factor. That is, a researcher seeks to make inferences about the specific levels of the factor included in the study and does not consider them random samples from a population of levels. For example, if a researcher compares different treatment groups or sets of experimental stimuli with different characteristics, the researcher's goal is to make inferences about the specific treatments implemented in the study or the stimulus properties that are manipulated.

The assumptions concerning the nested factor depend on whether it is considered to be a random or a fixed effect. Although in nested designs the nested factor is often considered to be random, there is no necessity to do this. The question of whether a factor should be treated as random or fixed is generally answered as follows: If the levels of a nested factor that are included in a study are considered to be a random sample of an underlying population of levels and if it is intended to generalize to the levels of the factor that are not included in the study (the universe of levels), then a nested factor should be treated as a *random factor*. The assumption that the levels included in the study are representative of an underlying population requires that the levels are drawn at random from the universe of levels. Thus, nested factor levels are treated like subjects who are also considered to be random samples from the population of all subjects. The resulting model is called a *mixed model* and assumes that the effects of factor B are normally distributed with a mean of zero, specifically:

$$\beta_{k(j)} \sim N(0, \sigma_{\beta_{k(j)}}^2). \quad (6)$$

A nested factor is correctly conceptualized as a *fixed factor* if a researcher only seeks to make an inference about the specific levels of the nested factor included in his or her study and if the levels included in the study are not drawn at random from a universe of levels. For example, if a researcher wants to make an inference

about the specific treatment centers (nested within different treatments) that are included in her study, the nested factor is correctly modeled as a fixed effect. The corresponding assumption of the *fixed model* is

$$\sum_{k(j)} \beta_{k(j)} = 0, \quad (7)$$

that is, the effects of the nested factor add up to zero within each level of factor A. The statistical conclusion is then conditional on the factor levels included in the study.

In both the mixed model and the fixed model, the variance for the total model is given by

$$\sigma_{\text{total}}^2 = \sigma_A^2 + \sigma_B^2 + \sigma_{\text{within}}^2. \quad (8)$$

In the population model, the proportion of variance accounted for by factor A can be expressed as

$$\omega_2 = \frac{\sigma_A^2}{\sigma_{\text{total}}^2} = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_B^2 + \sigma_{\text{within}}^2}, \quad (9)$$

that is, the variance caused by factor A divided by the total variance (i.e., the sum of the variance caused by the treatments, variance caused by providers, and within-cell variance). Alternatively, the treatment effect can be expressed as the partial effect size

$$\omega_{\text{part}}^2 = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_{\text{within}}^2}, \quad (10)$$

that is, the variance caused by factor A divided by the sum of the variance caused by the treatments and within-cell variance. The partial effect size reflects the effectiveness of the factor A independent of additional effects of the nested factor B.

The effect resulting from the nested factor can be analogously defined as partial effect size, as follows:

$$\omega_B^2 = \frac{\sigma_B^2}{\sigma_B^2 + \sigma_{\text{within}}^2} = \rho_I. \quad (11)$$

If the nested factor is modeled as random, this effect is equal to the intraclass correlation coefficient ρ_I . This means that intraclass correlations ρ_I are partial effect sizes of the nested factor B (i.e., independent of the effects of factor A). The intraclass correlation coefficient, which represents the relative amount of variation attributable to the nested factor, is also a measure of the similarity of the observations within the levels of the nested factors. It is, therefore, a measure of the degree to which the assumption of independence—required if the nested factor is ignored in the analysis and individual observations are the unit of analysis—is violated. Ignoring the nested factor if the intraclass correlation is not zero can lead to serious problems, especially to alpha inflation.

Sample Statistics

The source tables for the mixed model (factor A fixed and factor B random) and the fixed model (both factors fixed) are presented in Table 1.

The main difference between the mixed and the fixed model is that in the mixed model, the expected mean square for factor A contains a term that includes the variance caused by the nested factor B (viz., $n\sigma_B^2$), whereas in the fixed model, the expected mean square for treatment effects contains no such term. Consequently, in the mixed-model case, the correct denominator to calculate the test statistic for factor A is the mean square for the nested factor, namely

Table 1 Sources of Variance and Expected Mean Squares for Nested Design: Factor A Fixed and Nested Factor B Random (Mixed Model) Versus Factor A Fixed and Nested Factor B Fixed (Fixed Model)

Source	SS	df	MS	E(MS) Mixed Model	E(MS) Fixed Model
A	SS_A	$P-1$	$\frac{SS_A}{p-1}$	$\sigma_w^2 + n\sigma_B^2 + [p/(p-1)]nq\sigma_B^2$	$\sigma_w^2 + [p/(p-1)]nq\sigma_A^2$
B(A)	SS_B	$p(q-1)$	$\frac{SS_B}{p(q-1)}$	$\sigma_w^2 + n\sigma_B^2$	$\sigma_w^2 + [p/(q-1)]n\sigma_B^2$
Within cell (w)	SS_w	$pq(n-1)$	$\frac{SS_{\text{within}}}{pq(n-1)}$	σ_w^2	σ_w^2

Notes: The number of levels of factor A is represented by p ; the number of levels of the nested factor B within each level of factor A is represented by q ; and the number of subjects within each level of factor B is represented by n ; df = degrees of freedom; SS = sum of squares; MS = mean square; $E(MS)$ = expected mean square; A = factor A; B = nested factor B; w = within cell.

$$F_{\text{mixed}} = \frac{MS_A}{MS_B}. \quad (12)$$

Note that the degrees of freedom of the denominator are exclusively a function of the number of levels of the factors A and B and are not influenced by the number of subjects within each cell of the design.

In the fixed-model case, the correct denominator is the mean square for within cell variation, namely

$$F_{\text{fixed}} = \frac{MS_A}{MS_{\text{within}}}. \quad (13)$$

Note that the within-cell variation does not include the variation resulting from the nested factor and that the degrees of freedom of the denominator are largely determined by the number of subjects.

The different ways the tests statistics for the non-nested factor A are calculated reflect the different underlying model assumptions. In the mixed model, levels of the nested factor are treated as a random sample from an underlying universe of levels. Because variation caused by the levels of the nested factor sampled in a particular study will randomly vary across repetitions of a study, this variation is considered to be an error. In the fixed model, it is assumed that the levels of the nested factor included in a particular study will not vary across replications of a study, and variation from the nested factor is removed from the estimated error.

Effect Size Estimates in Nested Factor Designs

The mixed and the fixed models vary with respect to how population effect sizes are estimated. First, population effects are typically not estimated by the sample effect size, namely

$$\eta_A^2 = \frac{SS_A}{SS_{\text{total}}}, \quad (14)$$

and

$$\eta_{\text{part}}^2 = \frac{SS_A}{SS_A + SS_{\text{within}}} \quad (15)$$

for the nonpartial and the partial effect of the non-nested factor A, because this measure is biased in that it overestimates the true population effect. Rather, the population effect is correctly estimated with an effect size measure named *omega square*:

$$\hat{\omega}_A^2 = \frac{\hat{\sigma}_A^2}{\hat{\sigma}_A^2 + \hat{\sigma}_B^2 + \hat{\sigma}_{\text{within}}^2} \quad (16)$$

and

$$\hat{\omega}_{\text{part}}^2 = \frac{\hat{\sigma}_A^2}{\hat{\sigma}_A^2 + \hat{\sigma}_{\text{within}}^2} \quad (17)$$

for the estimated nonpartial and partial population effects of the non-nested factor A. The nature of the exact formula estimating the population effect on the basis of sample statistics depends on how the individual variance components are estimated in the different analysis of variance (ANOVA) models. In the mixed model, the variance components are estimated as follows (see also Table 1):

$$\hat{\sigma}_A^2 = \frac{(p-1)(MS_A - MS_B)}{npq}, \quad (18)$$

$$\hat{\sigma}_B^2 = (MS_B - MS_{\text{within}}) / n, \quad (19)$$

and

$$\hat{\sigma}_{\text{within}}^2 = MS_{\text{within}}. \quad (20)$$

As a result, the population effect size of factor A can be estimated by the following formula for the nonpartial effect size:

$$\begin{aligned} \hat{\omega}_{\text{mixed}}^2 &= \frac{SS_A - (p-1)MS_B}{SS_A - (p-1)MS_B + pqnMS_{\text{within}}}. \end{aligned} \quad (21)$$

Accordingly, the partial effect size for factor A can be estimated with the formula

$$\hat{\omega}_{\text{mixed,partial}}^2 = \frac{SS_A - (p-1)MS_B}{SS_A - (p-1)MS_B + pqnMS_{\text{within}}}. \quad (22)$$

In the fixed model, the population effect is also estimated by Equation 16, but the estimates of the factor A and nested factor B variance components differ from the mixed model (cf. Table 1), namely:

$$\hat{\sigma}_A^{2'} = \frac{(p-1)(MS_A - MS_{\text{within}})}{npq} \quad (23)$$

and

$$\hat{\sigma}_B^{2'} = \frac{q-1}{qn}(MS_B - MS_{\text{within}}). \quad (24)$$

As a consequence, the nonpartial population effect size of factor A for the fixed-effects model can be estimated by the following formula:

$$\hat{\omega}_{\text{fixed}}^2 = \frac{SS_A - (p-1)MS_{\text{within}}}{SS_{\text{total}} + MS_{\text{within}}}. \quad (25)$$

The corresponding estimated partial population effect can be estimated with the following formula:

$$\hat{\omega}_{\text{fixed,partial}}^2 = \frac{SS_A - (p-1)MS_{\text{within}}}{SS_A - (p-1)MS_{\text{within}} + pqnMS_{\text{within}}}. \quad (26)$$

Statistical Power in Nested Factor Designs

It is important to consider the implication of nested factor designs on the statistical power of a study. The consequences a nested factor design will have on the power of a study will vary dramatically depending on whether the nested factor is modeled correctly as a random or as a fixed factor. In the mixed-effects model, statistical power mainly depends on the number of levels of the nested factor, whereas power is largely independent of the number of subjects within each level of the nested factor. In fact, a mixed-model ANOVA with, for instance, a nested factor with two levels nested within the levels of a higher order factor with two levels for each treatment essentially has the statistical power of a *t* test with two degrees of freedom. In the mixed model, power is also negatively related to the magnitude of the effect of the nested factor. Studies with random nested factors should be designed accordingly with a sufficient number of levels of the nested factor, especially if a researcher expects large effects of the nested factor (i.e., a large intraclass correlation).

In the fixed model, statistical power is mainly determined by the number of subjects and remains largely unaffected by the number of levels of the nested factor. Moreover, the power of the fixed-model test increases with increasing nested factor effects because the fixed-effects model residualizes the *F*-test denominator (expected within subject variance) for nested factor variance.

Criteria to Determine the Correct Model

Two principal possibilities exist for dealing with nested effects: Nested factors can be treated as random factors leading to a mixed-model ANOVA, or nested factors might be treated as fixed factors leading to a fixed model ANOVA. There are potential risks associated with choosing the incorrect model in nested factor designs. The incorrect use of the fixed model might lead to overestimations of effect sizes and inflated Type I error rates. In contrast, the incorrect use of the mixed model might lead to serious underestimations of effect sizes and inflated Type II errors (lack of power). It is, therefore, important to choose the correct model to analyze a nested-factor design.

If the levels of a nested factor have been randomly sampled from a universe of population levels and the goal of a researcher is to generalize to this universe of levels, the mixed model has to be used. Because the generalization of results is commonly recognized as an important aim of statistical hypothesis testing, many authors emphasize that nested factors should be treated as random effects by default. Nested factors should also be treated as random if the levels of the nested factors are randomly assigned to the levels of the non-nested factor. In the absence of random sampling from a population, random assignment can be used as a basis of statistical inference. Under the random assignment model, the statistical inference can be interpreted as applying to possible rerandomizations of the subjects in the sample.

If a researcher seeks to make an inference about the specific levels of the nested factors included in the study, a fixed-effects model should be used. Any (statistical) inference made on the basis of the fixed model is restricted to the specific levels of the nested factor as they were realized in the study.

The question of which model should be used in the absence of random sampling and random assignment is debatable. Some authors argue that the mixed model should be used regardless of whether random sampling or random assignment is involved. Other authors argue that in this case, a mixed-effects model is not justified and the fixed-effects model should be used, with an explicit acknowledgment that it does not allow a generalization of the obtained results. The choice between the mixed and the fixed model is less critical if the effects of the nested factor are zero. In this case, the mixed and the fixed model reach the same conclusions when the null hypothesis is true even if the mixed model is assumed to be a valid statistical model for the study. In particular, the mixed model does not lead to inflated Type I error levels. The fixed-effects analysis, however, can have dramatically greater power when the alternative hypothesis is true. It has to be emphasized, however, that any choice between the mixed and the fixed model should not be guided by statistical power considerations alone.

Consequences of Ignoring Nested Factors

Although the choice between the two different models to analyze nested factor designs may be difficult, ignoring the nested factor is always a wrong decision. If the mixed model is the correct model and there are nested factor effects (i.e., the intraclass correlation is different from zero), then ignoring a nested factor, and thus the dependence of observations within the subjects within the levels of the nested factor, leads to inflated Type I

error rates and an overestimation of population effects. Some authors have suggested that after a preliminary test (with a liberal alpha level) shows that there are no significant nested factor effects, it is safe to remove the nested factor from the analysis. Monte Carlo studies have shown, however, that these preliminary tests are typically not powerful enough (even with a liberal alpha level) to detect meaningful nested-factor effects.

However, if the fixed-effects model correctly describes the data, ignoring the nested factor will lead to an increase in Type II error levels (i.e., a loss in statistical power) and an underestimation of population effects. Both tendencies are positively related to the magnitude of the nested factor effect.

NESTED SAMPLING

Nested sampling is a computational method for both generating samples from a posterior probability distribution and calculating the Bayesian evidence. The approach was invented by John Skilling in 2004 primarily for computing Bayesian evidence values, but nested sampling is now also widely used for parameter estimation from samples. Parameter estimation with nested sampling often performs well compared to alternative methods like Markov chain Monte Carlo for posterior distributions with multiple local maxima. Popular nested sampling software packages include MultiNest, PolyChord, and dynesty.

Background

Applications of Bayesian statistics in research can generally be divided into *model selection* and *parameter estimation*. Model selection involves working out which model of the data is most likely to be correct. This can be done by comparing the Bayesian evidence values for each model, given the data and any prior knowledge. Parameter estimation involves inferring the likely parameter values for a specific model, given the data. This is typically done by generating samples from the posterior distribution of parameters' values, then assessing the samples' properties.

Given a model and some data, both the posterior distribution of parameter values and the Bayesian evidence can be calculated using Bayes's theorem. For practical data sets and research applications, this must in general be done computationally, and nested sampling is one possible method.

The next section provides an overview of the procedure nested sampling uses to produce posterior samples. This is followed by a discussion of calculation uncertainties and of software packages that can be used to implement nested sampling in practice.

The Nested Sampling Algorithm

The algorithm begins by sampling some number of points randomly from the prior. It then iterates by, at each step, removing the point with the lowest likelihood and replacing it with a new live point sampled randomly from the region of the prior with a higher likelihood than the removed point. Iterating in this way until some termination condition is satisfied generates a list of samples with successively higher likelihoods; these are used to infer the properties of the posterior distribution and to calculate the Bayesian evidence.

The constraint that successive samples must have higher likelihoods means that each sample can be thought of as representing the region of the prior with likelihood values in between the likelihood values of the previous and subsequent samples. The region of the prior being sampled and the fraction of the prior being represented by each sample shrinks exponentially as the algorithm proceeds to higher likelihoods. The key insight of nested sampling is that the rate of this shrinkage, while not known exactly, can be estimated statistically. Furthermore, these statistical estimates of the fraction of the prior represented by each sample can be used to weight the samples. With appropriate weights, the samples can be viewed as weighted samples from the posterior and can also be used to calculate the Bayesian evidence.

Several modifications to the aforementioned nested sampling algorithm aimed at making it more computationally efficient have been proposed in the literature. One popular variant is *dynamic nested sampling*, in which the number of samples taken in different likelihood ranges is varied to maximize calculation accuracy by taking more samples in the regions with the most importance to calculation accuracy. Dynamic nested sampling can achieve large improvements in efficiency over standard nested sampling, especially for high-dimensional parameter estimation problems.

Estimating Uncertainties in Nested Sampling Results

In practice, there are three key sources of possible inaccuracy in nested sampling calculations. Firstly, there is some error from the statistical estimates of sample weights, which affects both Bayesian evidence calculation and parameter estimation from posterior samples. For parameter estimation only, there is an additional sampling error due to the finite number of points being sampled within a given likelihood range; for example, there may be many regions of the parameter space with very different parameter values but similar likelihoods.

If the nested sampling algorithm was implemented perfectly, then the aforementioned two sources of uncertainty would be the only significant causes of sampling error. However, in practice, the requirement to draw an uncorrelated sample from the prior with some likelihood constraint can be computationally challenging. Different nested sampling software packages use different approaches to drawing samples and often have additional settings controlling this process. If the software settings are not appropriate and the posterior distribution is difficult to sample (e.g., if it is high-dimensional and has multiple local maxima), then nested sampling software may produce correlated samples, resulting in additional errors.

Software Packages

In practice, researchers using nested sampling typically make use of existing software packages to perform the nested sampling algorithm. The researcher supplies their likelihood and prior distributions, and the software will perform the nested sampling algorithm and return weighted samples from the posterior and an estimate of the Bayesian evidence.

Many popular software packages implementing the nested sampling algorithm exist; three particularly popular packages are MultiNest, PolyChord, and dynesty. Such packages are well tested and optimized,

so using them is typically preferable to independently implementing the nested sampling algorithm. Dynesty performs dynamic nested sampling, which can have significant computational efficiency advantages over standard nested sampling. Software packages for estimating the statistical uncertainty of nested sampling results also exist; an example is nestcheck.

NETWORK ANALYSIS

Networks pervade all aspects of the world ranging from the distribution of blood vessels, through neural networks, social networks, and the World Wide Web. Complex systems are predicated on networks comprising interactions among the system's components. Consequently, to understand such complex systems, we need to understand the networks behind the systems. Network analysis comprises a broad range of analytical approaches, which can be conducted using simulated data or empirical data from research participants, for understanding system-level relationships. Network analysis has been used in causal attribution research and social network analysis for a considerable number of decades; however, it has gained wider application in psychological science, since the turn of the 21st century.

Network analysis has examined fundamental psychological constructs such as intelligence, personality, and psychopathology symptoms as well as psychometric measurement models. Denny Borsboom and colleagues' influential application of networks in the field of clinical psychology in relation to psychopathology symptoms has led to the growth of network research in psychology; they are critical innovators in network analysis theory, process, and applications.

This entry discusses networks generally and how networks are estimated and graphically represented. This entry also considers various ways network analysis can be applied in psychological science.

Networks

Networks can be estimated from data derived from different designs, including cross-sectional, longitudinal, and experimental studies. Furthermore, the analysis can be conducted on an individual (within-person) level or at a group level. Within-person network analysis provides insights into a specific individual over time. Group-level analysis can estimate the network structure of nodes and edges that represent a specific population, whereas between-group network analysis compares networks produced by different populations.

Psychological research examines patterns of relationship between variables: The network of relationships between the variables constitutes the psychological phenomenon to be understood using network analysis. Networks are structures comprising variables (represented by nodes) and the relationships (edges) between the nodes. Within the network literature, nodes are sometimes referred to as *vertices*, and edges are sometimes referred to as *links*. A node represents the variable of interest, which can be measured in a variety of ways. For example, the node may represent the response to a questionnaire, a clinician's rating of psychological state, observed behavior, activation in neural pathways, or levels of a specific hormone in the blood. The edge represents the nature of the relationship between the nodes. For example, it may reflect the comorbidity of psychological symptoms, the relationship between beliefs and behaviors, and the social connections between individuals.

Within a network, two types of edges are distinguished. A *directed edge* refers to the connection between the nodes indicating a one-way effect, represented by the head of the edge having a pointed arrowhead. In contrast, an *undirected edge* connects the nodes to reflect a shared relationship (e.g., correlation), but there is no indication of direction of effect. Networks may be fully directed (i.e., all edges are directed), fully undirected (i.e., no edges are directed), or mixed (i.e., both direct and undirected edges are present in the network). A directed network can be *cyclic* (i.e., one can follow the directed edges from a given node to end up back at that node) or *acyclic* (i.e., one cannot start at a node and end up back at that node again by following the directed edges).

Directed networks may denote causal relationships between variables; however, directed networks require

very stringent assumptions to be met. For example, all the causal variables are included in the network, and the causal chain of cause to effect is acyclic (i.e., a variable cannot cause itself in a network path). The acyclic assumption is probably not realistic for many areas of psychology, where mutual causal influences can exist between variables, for example, self-efficacy to perform a behavior results in that behavior, which then results in a higher sense of self-efficacy. Although many network models present plausible causal pathways, most network analyses in psychology examine undirected networks in cross-sectional data, which precludes causal claims being made. Studies using directed networks based on time-series data can at best show Granger causality (i.e., evidence based on predictive probability, which is consistent with a causal relationship but not a sufficient condition). The PC algorithm may be applied to find possible causal structures in the network that may have produced the patterns of relationships within the data; to date, this method has not been widely applied in network analyses of psychology data. At present, network analysis may be considered as providing a basis for making hypotheses about possible causal relationships between variables, which need empirical confirmation in subsequent studies.

Edges in the network also quantify the polarity and magnitude of the relationships between the variables in the network. The polarity of the relationship is typically represented graphically using different colored lines to represent positive (e.g., positive correlation between nodes is typically colored blue or green) and negative (e.g., negative correlation between nodes is typically colored red) relationships. Furthermore, an edge can be *weighted* or *unweighted*. A *weighted edge* represents the relationship strength (e.g., correlation) between variables by changing the thickness and color density of the line connecting them: Stronger relationships are represented by thicker, denser colored edges. An unweighted edge reflects the presence of a relationship without quantifying its strength; if the variables are not related, then there is no connecting edge between them in the network.

A simplified black-and-white-colored example of a network is provided in Figure 1. This network is based on the partial correlations between four variables (A–D). The different strength and polarity of the correlations are represented by the different thickness (weight) and nature (i.e., broken line or straight line) of the edges between the variables. As the data are based on bivariate correlations, the edges are unidirectional. Both positive (straight lines) and negative correlations (broken lines) are present in the network. Within this example, variable B is more central and has more

Figure 1 Network Model Representing the Partial Correlation Matrix Between Four Variables (A–D).

connections as it correlates with all the other variables in the network, whereas variable D is related to just one variable.

Representing the Network

Network analyses visually represent the patterns of relationships between the variables and use graph theory to consider the statistical properties of the network. The network is estimated using statistical indices that assess relationships (e.g., correlations). Networks estimated using correlation coefficients may have spurious edges between variables, caused by the effects of an unmeasured confounding variable that influences both of the connected nodes. To address this issue, partial correlations are commonly used as they quantify the relationships between variables and control for the influence of the remaining variables in the analysis. Consequently, possible confounding variables need to be assessed to make sure that they are statistically controlled in the analysis. The aim is to produce relationships between variables that are not explained by the remaining variables in the model.

The analysis of undirected network models typically applies a different pairwise Markov random field (PMRF) model; the type of model will vary according to the nature of the data (continuous, ordinal, binary, or mixtures of different data) being examined. For multivariate normally distributed continuous data, the Gaussian graphical model (GGM) can be used to analyze the partial correlations. Where continuous data are not normally distributed, appropriate transformations (e.g., nonparanormal transformation) can be run on the data before using the GGM. If the data are ordinal, then the GGM can also be used as the network will be based on the polychoric correlations instead of partial correlations. The Ising model can be applied if the variables are binary. For data containing both categorical

and continuous variables, the mixed graphical model is used. In general, networks based on PMRF models can be developed using all types of data.

The number of variables in the model and the complexity of the resultant network are key issues. The more variables in the model, then the more edges have to be estimated; however, in large networks, many of these edges may be spurious. A statistical regularization process is applied to minimize the number of spurious edges in the data. A least absolute shrinkage and selection operator (LASSO) is frequently used in the analysis of partial correlations to generate a network, which contains only the strongest relationships between the variables. The graphical LASSO is frequently used as it can be run in specific analysis programs, and it can handle noncontinuous data.

The LASSO will reduce the number of connections in the network: Its sparseness is determined by a tuning parameter (λ), which the researcher selects, with higher λ values removing more edges from the network. Therefore, in selection of the λ value, the researcher tries to reduce the spurious edges while maximizing the number of true edges in the network. To optimize this process, networks are estimated using a range of λ values, ranging from a dense network with every node connected to each other to a network where no nodes are connected. To pick the optimal model from this collection of networks, the extended Bayesian information criterion (EBIC) is commonly applied in network analysis of psychological data using both the GGM and Ising models.

Graphing the Network

The network graph should arrange the nodes and edges to represent the nature of the empirical relationships among them. The Fruchterman-Reingold algorithm, which is commonly used in psychology research, produces an optimal layout of nodes, wherein nodes that have strong relationships are positioned close to each other, and those with weak relationships are positioned further apart. The shape of the network highlights the structural relationships between the nodes, and it can be analyzed in terms of its characteristics.

Some nodes may be more important (central) than others in creating the network's structure. Centrality indices, expressed as standardized z scores, reflect the relative importance of a given node in the network. Judging centrality requires careful consideration of its different dimensions in combination.

Degree centrality is the number of edges for a given node. *Node strength* reflects how strongly a node is directly connected to other nodes, based on the sum of the weighted number and strength of all connections of

a specific node relative to all other nodes. Degree centrality quantifies the number of connections, whereas node strength gives other information on the node's importance. For example, a node with many weak relationships may be less central compared to a node that has a smaller number of very strong relationships. Degree and strength should both be considered in evaluating a node's centrality.

Closeness assesses the average distance of a specific node to all the other nodes in the network. A central node that has a high closeness value indicates a variable that is influenced rapidly by changes to variables in any part of the network, but also that changes in this variable will change the other variables quickly. *Betweenness* indicates the importance of a given node is in relation to the average connection between other nodes. A node may have an important role if it is positioned on the shortest path between two other nodes and influences the connection that the other nodes have between them.

Clustering relates to whether the node is included in a cluster or is isolated from the rest of the nodes. The local clustering coefficient C is the proportion of edges that exist between the neighboring nodes of a particular node relative to the total number of possible edges between neighbors. Where nodes form clusters, C may indicate that some nodes within the cluster are potentially redundant. For example, if the node is removed from the network, can the remaining nodes in the cluster still influence each other? In addition to local clustering in the network, a clustering coefficient (also called *transitivity*) can also be estimated for the entire network. Of note, *communities* may be present in the network; a community is a clustering of nodes that have strong relationships to each other but are weakly related to other nodes in the network.

Networks can have any shape, but a number of common network shapes are reported frequently. *Random networks* are characterized by nodes that have random connections, and the distribution of the node's connections follows a normal curve. *Small-world networks* have high levels of transitivity, with the nodes connected with each other through small average path lengths. A common illustration of a small-world network relates to the famous "six degrees of separation" principle whereby letters were successfully sent from individuals to others to reach a designated target person: Approximately six steps were required as the individuals (nodes) were connected by a short path through the network. *Scale-free networks* have in essence two categories of nodes: A small number of nodes, which act as *hubs*, have an extremely high number of connections to the other nodes, while the majority of ordinary nodes have a very small number of connections in the

network. In contrast to the normal curve distribution of the random networks, the nodes in a scale-free network reflect a power-law distribution.

Network Accuracy

When a network is estimated using empirical data from a sample of participants, the accuracy of the network in terms of the nature and patterns of links between the variables needs to be evaluated. As much psychological research has relatively small sample sizes, the network analysis may not accurately estimate the edge weightings and node centralities. Consequently, similar to all sample-based estimates of population parameters, one needs to examine the accuracy of the estimates using confidence intervals (e.g., 95% CI), which can be generated using bootstrapping methods: the wider the CI, the harder it becomes to interpret the edge strength. Either a parametric bootstrap or nonparametric bootstrap can be applied for edge weights. A parametric bootstrap samples data from a parametric model estimated using the original data to develop the sampling distribution; however, this can only be applied to a parametric model, which limits its applicability. A nonparametric bootstrap is data-driven and can be applied to a wide range of data, including continuous, categorical, and ordinal data. It generates less-biased estimates for the frequently derived LASSO regularized edges and therefore is widely applicable in the literature.

Assessing the accuracy of the centrality estimates uses another type of bootstrap. Subsamples of the original data are examined to assess the stability of the order of the centrality indices across these samples (*m out of n* bootstrap). The order of the centrality indices should stay the same after the network is estimated with fewer participants in the subsamples. A case-dropping bootstrap could be used on the data to create various size subsamples (e.g., 95% of the original sample, 90%, 50%, . . . 10%), and the correlation between the estimates from the overall data with each of the estimates from the subsamples can be calculated. The correlation stability (CS) coefficient assesses the correlation between the original full sample data set and these subsamples; a CS of .7 or higher between the original full sample estimate and the subsample estimates indicates a high correlation and is recommended.

Applications of Network Analysis

Although network analysis has been most frequently applied to cross-sectional data from a single group, it can also be used to compare networks estimated for

different groups. Methods for comparing networks from different groups have been recently developed, such as the fused graphical LASSO. Furthermore, the Network Comparison Test facilitates comparisons of two networks from different groups using permutation testing to compare if the groups' networks differ regarding the network overall structure, edge strengths, and the levels of connectivity.

Network analysis can also be applied to individual-level data; a within-person network uses time-series data to develop a network of relationships between variables over time. Such a network can estimate the effects of time and changes in variables between the data assessments. A graphical vector autoregressive (VAR) model applying an LASSO regularization, based on the Bayesian information criterion to select the optimal tuning parameter λ , can be used to estimate a within-person network. In more complex designs with multiple individuals assessed longitudinally, multilevel VAR models can estimate the variation in the network related to the effects of individual differences between individuals as well as the effects of time.

Regardless of the context of the network analysis, it is critical to note that the network model is a representation of a psychological process. Therefore, it is essential that the most salient variables for that process are included and the psychometric properties of their measures are carefully considered in order to minimize error in the network analysis. In line with general concerns regarding reproducibility of findings in psychological research, researchers should assess both the stability of the networks generated from sample data and the generalizability of the network model. The development of helpful thresholds for accuracy and stability indices will enhance understanding of the network. As network analysis in psychology is relatively recent and the method is still evolving, in the majority of situations, it is not straightforward to develop clear hypotheses about the expected network structure and edge weights. Consequently, statistical power calculations to guide sample size decisions are challenging. It is hoped that as researchers use network analyses in multiple areas of psychology, a better sense of the network structures and edge weights that might be expected in a given context will be developed.

The most common approaches to estimating networks in psychology have been based on undirected relationships (e.g., partial correlations) between variables. The use of causal modeling approaches can provide deeper insights into the possible directional relationships in the network structure. Given its recent development, network analysis in psychology has typically focused on exploratory approaches to network estimation from data; future research can advance the

literature by applying confirmatory network modeling to test hypothesized network structures.

Network science provides a broad framework to productively examine complex systems: Psychological processes reflect complex systems of interconnected variables, and to understand such systems, one needs to understand the networks that define the interactions between these variables. Network analysis provides a means to understand system-level relationships in a manner that can enhance psychological science and practice.

NETWORK BOUNDARIES

Boundary specification is a crucial task that social network researchers must decide before data collection begins. Some networks have clear membership requirements (e.g., the 23 pupils in Miss Miller's second grade class, the 46 soldiers of Second Lieutenant Jones' platoon). But most informal social networks lack clear-cut criteria for identifying all participants. For example, organized crime networks have fuzzy boundaries, as criminal entrepreneurs interact across diverse contexts with criminals and noncriminals. For an investigation of interagency wildfire response networks in the

Northwest of the United States, network size and composition would differ greatly if researchers bounded the network using either legal jurisdictions in geographic areas at-risk for large wildfires or event-based responses of organizations to a specific set of wildfires.

Network methodologists have proffered several boundary specification strategies to consider when designing research on informal social networks. In two seminal boundary specification articles, Edward Laumann, Peter Marsden, and David Prensky compared realist and nominalist strategies for specifying the “inclusion rules in defining the membership of actors in particular networks and in identifying the types of social relationships to be analyzed” (1983, p. 19). They subsequently, in 1989, distinguished among positional, relational, and event-based strategies. More recently, Branda Nowell et al. (2018) proposed a framework “for aiding network scholars working in complex problem domains” (p. 1). This entry summarizes the advantages and disadvantages of alternative boundary specification methods and provides several examples.

In the *realist strategy*, researchers seek to adopt the viewpoints of network actors themselves about which persons, groups, or organizations are the network’s participants. Entities and relations are included when other actors consider them pertinent and excluded if they’re viewed as unimportant. In applying the *nominalist strategy*, investigators deploy a theoretical or conceptual standard to decide whether entities are inside or outside a network. Legal restrictions or formal membership requirements may generate a roster or list of participants, such as invitees to a charity gala or registrants attending a professional conference. If applied to the same network, the realist and nominalist strategies typically would result in different but partially overlapping network boundaries.

Positional strategies use actor characteristics, organizational job titles, or the occupancy of a distinct role as boundary-specification principles. Positional approaches often generate a set of actors holding equivalent positions within a social structure, even if many actors lack ties to one another. For example, enumerating all elementary school teachers in a district would result in many small, densely connected networks within each school building and relatively fewer ties connecting teachers working at different schools. Another limitation of the positional strategy is that organizational membership lists may be incomplete or not up to date. Researchers may have to assemble a complete list of positional participants before proceeding to data collection.

Relational strategies use knowledgeable informants or network actors to nominate additional actors

for inclusion. Under this heading are reputational, snowball, and event-based methods for setting boundaries. Researchers who apply the *reputational method* find experts or knowledgeable informants to identify a set of entities as network participants. To void idiosyncratic nominees, multiple mentions may be required for inclusion. Another approach is to present an expert panel with a predetermined list and request additions and deletions. Reputational methods run the risk that insufficient informants are available or willing to disclose all the important network participants.

Snowball samples start with a small nonrandom subset of network actors who are requested to name others having a particular type of relation, such as friendship or seeking financial advice. Those nominees are contacted and asked to name others with whom they have the same type of ties. Across successive waves the network grows larger, like a snowball rolling downhill. The process halts when no additional names appear. Since each successive wave is generated from existing members’ ties, a snowball strategy will generally result in a dense network. One disadvantage is its inability to find truly isolated individuals. If the initial set of seed names is poorly representative of the network, the snowball may fail to find small, disconnected network components. Snowball sampling is often used to identify networks among hidden populations, such as homeless people, opioid abusers, street prostitutes, or cat burglars. Another problem of snowball sampling is ethical issues raised by asking new recruits to provide information about their contacts in the absence of those contacts’ informed consent. Some internal review boards may not approve research that recruits new contacts directly. Instead, respondent-driven studies can ask recruits to give each of their referrals a coupon offering a small token, such as a gift card, for participating in the study.

As an alternative to relying on actors or experts to identify network boundaries, *event-based strategies* focus on one or more activities that occur at specific times and places. The boundary is determined by the set of persons, groups, or organizations who participate in those activities. A key issue is deciding which events to select: a too-narrow set of events may exclude some important players who were unable to attend, while a too-broad set may encompass numerous trivial participants. A “Goldilocks” solution is to combine realist, reputational, and event-based strategies by using both participants and experts to advise researchers on a judicious selection of activities that would likely yield a comprehensive combination of entities, relations, and events comprising the network of interest.

NETWORK COMPOSITION

The term *social network* refers to a social structure made up of interconnected actors. These actors can be individuals, groups, cities, organizations, or even online communities. Social network research is the study of the relationships and network positions between social actors in identifiable social structures. Since the early 1980s, the application of social network methods has grown exponentially. This increased interest has led to sophistication in both the design and analysis of social network research. This entry focuses on the design aspect—that is, the composition of networks. It describes three critical components of social network research—*nodes*, *ties*, and *boundaries*—and outlines recommendations for improving the validity of inferences drawn from this research.

(a) Microlevel Network

(b) Macrolevel Network

Figure 1 Micro- and Macrolevel Networks

Components of Social Networks

Social network research generally focuses on understanding one or a combination of three components of a social network: nodes, ties, and boundaries. These components provide social network scholars with the foundations for digesting existing research and designing their own social network studies.

Nodes

In social network research, nodes are the actors (e.g., individuals, groups, firms) within a network. A node can either be an individual actor or a collective of actors, depending on the study's analysis level. For microlevel studies, nodes are the individual actors in the network. In Figure 1a, the three nodes are individual doctoral students within a cohort. For macrolevel research, nodes are often defined as collectives of actors, such as groups or organizations. Figure 1b shows three collectives of actors (e.g., students) connected as nodes in a macro network (e.g., schools). For meso-level research, nodes combine the characteristics of nodes at micro- and macrolevels. For instance, board directors of one firm connect their organizations to others through shared board membership.

Ties

Network ties refer to the relationships between nodes in a social network. Two broad classifications of ties have been identified in the literature: relational states and relational events. *Relational states* can further be classified into either similarities or social relations. *Similarities* occur when two actors share attributes such as demographic characteristics, attitudes, locations, or group membership. *Social relations* are ties based on the nature of interpersonal relationships between two actors. In social network research, scholars have examined three types of social relations: roles, affect, and cognition. Role ties (e.g., friendship) reflect the role of an actor in a relationship. Affective

ties (e.g., dislike) are based on social actors' feelings about one another. Finally, cognitive ties (e.g., trust) are based on the cognitive awareness of actors. *Relational events* are also classified into two categories: interactions and flows. *Interactions* are observable behaviors directed toward other actors (e.g., advice-giving). *Flows* refer to the resources and outcomes of interactions (e.g., knowledge).

Boundaries

Network boundaries reflect the structure of the network, specifying what nodes are included in a network. Network boundaries can be specified based on a combination of three rules: positions, events, and relations. Using a *position* rule requires researchers to define nodes based on formally defined roles in the social system (e.g., a network of doctoral students in a business school). An *event*-based rule involves defining the boundaries of the network by the presence of actors at a particular event (e.g., doctoral students who attended a doctoral student consortium at a conference). Finally, a *relation*-based rule involves defining boundaries based on specific shared relationships. This approach typically begins with the specification of a small set of seed nodes and then expands to include others who share a specific relationship with the seed nodes (e.g., firms' cofounders and their previous cofounders).

Improving the Validity in Network Research

As with other types of research, social network research needs to pay attention to statistical validity, which is an important property of causal inferences that ensures conclusions respond correctly to the real world. When studies are poorly designed, all four types of validities—construct, internal, statistical conclusion, and external—are adversely affected.

Construct validity refers to the coherence between a construct of interest and its operationalization. A major threat to construct validity in network research is the inappropriate operationalization due to the inadequate explication of a construct. Violations of construct validity may take the form of a researcher measuring microlevel networks (e.g., managers' relationships with other managers in an organization) in studies about macrolevel networks (e.g., managers' relationships with managers in other organizations). To avoid this, researchers need to define a construct clearly and measure it appropriately.

Internal validity refers to the validity of inferences about whether observed relationships reflect a causal relationship. The internal validity of network research

could be affected by several factors, including attrition, bias selection, ambiguity in causal direction, and omitted variables. Because social network research often requires long periods to collect data, internal validity may be violated when a substantial number of participants drop out of the study. To mitigate threats to internal validities, researchers should be careful about sample selection, usage of control variables, and boundary specification.

Statistical conclusion validity refers to inferences about the causal relationship between treatment and outcomes. In network research, threats to statistical conclusion validity generally arise from applying inappropriate statistical techniques or adopting inappropriate experimental treatments. For example, fishing for statistically significant relationship (e.g., include irrelevant control variables) and hypothesizing after results are already known. To reduce the effect of this threat, researchers should utilize the most appropriate statistical techniques in their studies.

External validity focuses on whether causal inferences can be generalized across samples and settings. Violations to external validity in social network research occur when the relationship observed is related to the location of the study (e.g., South America or North America). Given that social network research seeks to understand actors in a unique system, researchers can improve external validity by collecting data from multiple samples and defining and controlling for the context in their studies.

Final Thoughts

Since the early 1980s, the application of social network methods has increased exponentially, and recent reviews reveal that this trend is not abating. This entry explained the three fundamental components of social networks—nodes, ties, and boundaries. It highlighted fundamental validity issues that may arise in social network research and possible ways to mitigate these validity issues. With an understanding of the foundations of network composition and the extant literature, researchers can appropriately design and execute their social network research.

NETWORK DENSITY

Network density is the proportion of direct ties (connections or relationships) to the total number of potential ties among members of a network. The members of a network are usually individuals, organizations, or other things depending on the context being studied. Network density can vary from dense to sparse (also referred to *closed* or *open*). Dense networks have a high proportion of direct ties to total ties, which is typically characterized by significant sharing and commonalities among network members. Sparse networks have a low proportion of direct ties to total potential ties, which is usually indicative of members who have a low level of sharing and have little in common. Network density, like other social network characteristics, provides insight into the workings of a network that can influence thoughts and behaviors of its members. This entry describes network density and the history of social network analysis, network density's primary characteristics, antecedents, outcomes, and aspects of its empirical investigation.

Social Network Analysis

Network density is one measure of a network's structure and is used along with many other measures (e.g., betweenness, centrality) to study the antecedents and outcomes of networks. Network density is used extensively in social network analysis in different areas of sociology, but also in many other areas such as geography, economics, organizational studies, medical and health, and political science. Social networks are considered to influence the thoughts and behaviors of network members by acts such as the sharing of information and providing of help. These acts can be beneficial to a network member, but they can come at a cost in the form of time and expectations.

Social network analysis originated in the late 1800s and early 1900s with the work of Georg Simmel and Émile Durkheim. One of the views purported by Simmel was the importance of being a member in both small and large networks—that each has something unique to offer. Durkheim also pointed to the importance of social interactions and the structures of networks. In the second half of the 1900s, social network analysis became more comprehensive and formalized based on the ties (relationships) between network members. In this time period, two key network characteristics were identified—strong ties and weak ties. The benefit of strong ties, when close connections exist, was described by David Krackhardt as providing help between network members. The benefit of weak ties, when network members are not well known to each other, was described by Mark Granovetter as providing access to distinct information to network members. Thus, the strength of a tie influences the benefits and costs of being in a network. Network density takes this idea one step further and describes how the proportion of ties within a network influences not only the benefits received but the disadvantages as well.

Network Density Effects

Through communication and action, network members build up understandings of and obligations to one another that guide their cognitions and behaviors in both a restrictive and supportive manner. This is more likely to occur when the relationships among network members are numerous and rich. Dense networks describe this type of network structure. With extensive ties and frequent interactions among network members, members become more fully aware of the thoughts and actions of other members. This provides social cohesion whereby members feel part of a unified group. As part of this group, they are obligated to help one another but also make sure that others are acting in an acceptable manner. Thus, dense network members benefit from the assistance of other members, but they also face limitations in their own behavior.

Less dense, or sparse, networks have fewer connections among members. These members also interact less frequently, which leaves less opportunity to feel a part of a group. This provides little in the way of feeling a responsibility to help one another. However, it does have the advantage of providing access to new, distinct information since the connections are less overlapping. This information access can benefit the network members by helping them come up with new ideas, for example. Social network analysis refers to unique connections between parts of a network as structural holes. Structural holes are valuable, as they provide an

information conduit between disparate parts of the network. Ronald Burt has written extensively about structural holes in the late 1900s and early 2000s.

Methodology

Approaches to empirically assessing network density have evolved along with social network analysis. Network density is calculated from the overall network data collected in a study. Researchers identify where relationships (connections) exist within a network, and this information is entered into a database that is used to compute a variety of network measures, such as centrality and betweenness, in addition to density. There are a number of software programs available that can compute the numerous network characteristics (e.g., UCINET) and provide visual displays of the networks. The basic computation of density would be the number of actual relationships divided by the total potential relationships. As an example, if there are six members in a network, that means there are 15 possible relationships in the network. If there are a total of 12 connections, the density measure would be .80 (12 relationships/15 possible relationships). If there are only three relationships, the density would be .20.

In addition to the early focus on the degree of helping and information sharing that occurs with different degrees of network density, more types of relationships have begun to be investigated. For instance, two coworkers may work together on various work tasks, but they may also have a social relationship outside of work. When more than one type of relationship exists between network members, it is termed a multiplex relationship. Multiplex relationships possess added complexity, but they also offer additional information for researchers that can help to better explain certain phenomena. Multiplexity and the existence of multiple overlapping networks have created many opportunities for researchers to more thoroughly investigate the influence of social networks.

NETWORK DISTANCE

Network distance refers to the distance between pairs of actors or players in a given network. Network distance is an important concept in the field of social network analysis (SNA), which is an essential subject in social science research design. However, before delving into the details of network distance and its measurement in SNA, this article begins with a well-known example of a social science study of network distance, which has been drawing great interest from the scientific community as well as the general public.

The study is called the *small world experiment*, which is perhaps one of the earliest social science studies to investigate the network distance between people. To determine the connectivity of any random pairs of people in the United States, social psychologist Stanley Milgram asked volunteers in the Midwest to relay a briefcase to a stockbroker in Boston, MA. The volunteers were given a description of the target but not the address, and they were only allowed to pass the briefcase on to somebody they knew on a personal basis and those they thought would be closer to the target. It took, on the average, five intermediary steps before the briefcase reached the target. Thus, Milgram contended that every American is connected to everybody else within the United States through no more than five intermediary steps.

Milgram's small world experiment generated a great deal of interest and inspired many to follow suit. For example, the *Bacon number* calculates the path length that connects any actor to Kevin Bacon in a network of coappearances in the same movie. The advent of the Internet and social media networks seems to make the *small world* even smaller, with researchers noting that the average path length connecting any two Facebook users in the world is 4.74.

Network Distance in Social Network Analysis

As stated earlier, network distance is an important concept in SNA, which includes two main approaches: egocentric network (or ego-net) and whole network (also called *full network* or *complete network*).

Describing the differences between egocentric and whole network studies is beyond the scope of this entry, so this entry focuses on network distance in the whole network studies. Whole network studies have developed some measurements of network distance between pairs or dyads of actors or nodes in a given network.

Several important measures of social distance between dyadic pairs in whole networks exist, such as path, path length, and geodesic distance. A path in a network is a route across the network that runs from node to node along with the connections or ties of the network. However, such definition includes those paths that visit nodes or ties more than once. Thus, social network analysts produce a rigorous definition of path, often dubbed as self-avoiding paths, in which no node and no tie appear more than once. Paths exist in both directed and undirected networks. In a directed network, each tie or connection traversed by a path must be traversed in the correct direction for that tie. In an undirected network, ties can be traversed in either direction.

Path length is simply the number of ties or connections traversed along the path (note that it is not the number of nodes). For a given pair of nodes in a given network, multiple paths may exist, which means multiple path lengths may be present. Here, an important measure of network distance between pairs of nodes called *geodesic path* emerges. Geodesic path is the path with the lowest path length between a pair of nodes in a network. In other words, geodesic path, also called the *shortest path* or *shortest distance*, is a path between a pair of nodes for which no shorter path exists. Not all pairs of nodes have geodesic paths; some pairs are not connected with each other. In those cases, their geodesic paths are infinite. Also, geodesic paths are always self-avoiding paths because if a path intersects itself, it contains a loop. Removing the loop can shorten the path while maintaining the connection between the starting and ending node.

Examples

To illustrate those measures of network distances between pairs of nodes, this entry uses two artificial examples: one is undirected, and the other is directed network. Figure 1 shows the undirected network with six nodes.

Figure 1 contains 6 nodes and a total of 15 dyadic pairs ($C_6^2 = \frac{6!}{2! \times 4!} = 15$). For illustration, let's focus on the dyadic pair of nodes A and C. A total of four paths appear; each has a path length: A-B-C (2), A-B-E-D-C (4), A-E-B-C (3), and A-E-D-C (3). All those paths are self-avoiding paths because no node or tie is visited

more than once. However, only one path (A-B-C) is the geodesic path because it has the lowest path length (2). All other paths have a higher path length than the geodesic path between the pair.

Next, let's take a look at the directed network, illustrated in Figure 2.

Because this is a directed network, all ties have an arrow pointing from one node to another. Two mutual-ty ties (AB and AE) appear, meaning that the relationship is reciprocated between A and B, and between A and E. Notice also that although D is a recipient of relations, it is not the sender of any ties, engendering the path, path length, and geodesic path originating from D to other nodes in the network infinite.

Take a look at the dyad of B and D; two paths appear from B to D: B-C-D (2) and B-A-E-D (3). Geodesic distance from node B to D is thus B-C-D because its path length of 2 is the lowest. Another dyad from E to C has only one path (E-A-B-C) with path length of 3, which is also the geodesic path from E to C. However, reverse path from C to E does not exist, making

Figure 1 An Artificial Illustration of a Binary Undirected Network With 6 Nodes

Figure 2 An Artificial Illustration of a Binary Directed Network With 5 Nodes

such pair from C to E infinite in the measures of its path, path length, and geodesic distance.

NETWORK MATRICES

Network matrices are defined by Robert A. Hanneman and Mark Riddle (2005) as collections of elements into rows and columns, and they are often used in network analysis to represent the adjacency of each actor to each other actor in a network. To talk about network matrices, it requires some background information on networks and graph theory. According to Stephen P. Borgatti and colleagues (2018), “networks are a way of thinking about social systems that focus our attention on the relationships among the entities that make up the system, which we call actors or nodes” (p. 2). In the case of social sciences, actors or nodes are typically people. These actors have characteristics, such as gender and race/ethnicity, and the relationships between them also have characteristics, for example, friendship ties and support ties. Borgatti and colleagues (2018) argued that part of the power of the concept of a social network is that it provides a mechanism, which they

call “indirect connection” (p. 2) by which disparate parts of a system may affect each other. In extent, social network analysis is a social science that is primarily concerned with the structure of social networks and the position of actors within those networks.

Networks can be represented mathematically as graphs that consist of two sets: a set of vertices (nodes or actors) and a set of edges (links or ties) connecting the vertices. The field of mathematics concerning the study of graphs is called “graph theory.” In social network analysis, networks may be represented as graphs or matrices. Generally speaking, a matrix is a rectangular arrangement of a set of elements or entries such as numbers or symbols that are arranged in rows and columns. The dimensions of the matrix in Matrix 1 are three by four (3×4), as there are three rows and four columns. When discussing matrices, it is conventional to designate the number of rows as m and the number of columns as n and refer to the rows before the columns when describing the full size of a matrix. For example, Matrix 1 is a 3 (rows) $\times$ 4 (columns) matrix, which designates its full size.

In social network analysis, the most commonly used form of matrix is the adjacency matrix. It is called “adjacency matrix” because the entries indicate whether two nodes are adjacent or not. Most social network matrices are square with as many rows and columns as there are nodes in a data set. The elements or entries in the cells of the matrix record information about the ties between each pair of nodes. An adjacency matrix may be symmetric or asymmetric. For example, the matrix in Matrix 2 represents a friendship network. The rows represent the source of directed ties, and the columns

Matrix 1 Example of a 3×4 matrix

12	52	24	23
8	33	14	22
5	56	44	21

Matrix 2 Asymmetric adjacency matrix

	Node 1	Node 2	Node 3	Node 4	Node 5
Node 1	-	1	1	0	0
Node 2	1	-	0	0	0
Node 3	0	0	-	1	1
Node 4	0	1	0	-	1
Node 5	0	1	1	1	-

the targets. Node 1 nominates Nodes 2 and 3 as friends, but Node 3 does not reciprocate the friendship nomination. Therefore, this is an asymmetric matrix with directed friendship ties. If the ties represented in the matrix were undirected (e.g., ties representing the relation *are married to* or *talked to* where direction does not make sense), the matrix would necessarily be symmetric. The simplest matrix is binary, which means that if a tie is present, a one (1) is entered in a cell and if there is no tie, a zero (0) is entered. The first row and first column are not really parts of the matrix in Matrix 2, but social scientists typically show their data as an array of labeled rows and columns for presentation purposes.

Adjacency network matrices are always square, as shown in Matrix 2. They are also called one-mode matrices, as both the rows and columns refer to the same single set of nodes. However, in a two-mode matrix, the rows and columns refer to different sets of nodes. For example, imagine the nodes in the Matrix 2 rows voting for different election candidates rather than selecting friends among one another. In this case, the columns would correspond to different candidates.

Matrices can be described as having ways and modes. The ways represent the dimensions of the matrix, as when there are rows and columns, whereas the modes represent kinds of entities. A three-way matrix would then have rows, columns, and levels. Going back to the election example, suppose a researcher has data indicating which persons voted for particular candidates in different elections. This could be represented by a three-way, three-mode matrix, as in a data cube. Most studies, however, employ one-mode matrices, which are the simplest to use. Overall, graphs or networks can be represented in matrix form, and mathematical calculations can then be performed to summarize the information in the graph that is useful in unpacking patterns of ties in social networks.

NETWORK META-ANALYSIS

Network meta-analysis (NMA), also sometimes termed *multiple treatment meta-analysis* or *mixed treatment comparisons*, has emerged as a powerful statistical technique to compare treatments. NMA creates an evidence network to compare multiple treatments simultaneously by analyzing studies, which made different comparisons, in the same analysis. NMA is appropriate for situations in which there are multiple treatment options available, as it provides a comprehensive understanding of treatment effects by considering all available evidence; furthermore, it is possible to explicitly rank treatments in order of effectiveness. This entry further defines NMA by providing an example and graphical representations. It then reviews NMA assumptions and concludes by discussing the conduct and reporting of an NMA.

Example

In an oversimplified example in Figure 1, we have two treatments (Treatment 1 and Treatment 2) and usual care comparison groups. One study directly compared Treatment 1 with usual care in relation to an outcome, which allows us to estimate the difference between them. In this example, the mean difference between the treatment group ($M = 30$) and the usual care control group ($M = 20$) was 10 units. Another study directly compared Treatment 2 ($M = 26$) with usual care ($M = 22$) in relation to the same outcome and reported a four-unit mean difference. Although no study has directly compared Treatment 1 with Treatment 2, NMA allows us to create an evidence network structure as per Figure 1 to conduct an indirect comparison between Treatments 1 and 2 to estimate the difference between their effects in relation to the outcome dependent variable: Treatment 1 is estimated to have a six-unit mean difference to Treatment 2.

The distinction between direct and indirect effects may not be that meaningful once the network grows in complexity (e.g., comparing over 20 treatments): Evidence that is indirect for one comparison may be direct for another, and evidence on a single comparison may impact estimates of the treatment effects throughout the whole network. The most important issue is to

Figure 1 Example of Direct and Indirect Comparisons Between Treatment 1, Treatment 2, and Usual Care Control Group

include all the trials comparing the treatments of interest in the target population. The totality of the evidence in the network determines the estimates of the treatment effects between all treatments.

The NMA network is usually visually represented by a network plot, which can take on different shapes. Similar to other types of network analysis, there are conventions regarding the visual representation of the evidence network. A network comprises nodes (circles) connected by edges (straight lines). In NMA, each node represents each treatment condition, and the size of each node reflects the overall number of individuals in the included studies who received that specific treatment; the larger the number of individuals, then the larger the node for that treatment in the network. The edges are the lines that connect the nodes; solid lines reflect that direct comparison data are available between the connected node, and the thickness of the line reflects the number of studies that have made the direct comparisons, with thicker lines equating to more studies. Broken or dotted lines indicate indirect comparisons between nodes.

Similar to other network analytical approaches, the graphical representation of the evidence network highlights critical characteristics in the shape of the network. Figure 2a shows that Treatments 1, 2, and 3 have all been compared against each other in existing studies, and thus, each comparison in the closed loop (1 vs. 2, 1 vs. 3, 2 vs. 3) is informed by both direct and indirect evidence. Figure 2b illustrates a star-shaped network, in which four treatments have been

compared with a usual care group but have not been compared with each other. The size of the circles (nodes) reflects the different number of participants in the groups. Treatment 1 is small because fewer participants have received that treatment, whereas a large number of participants have received Treatment 4. The size of the line connecting the nodes varies because the number of studies making the comparisons between the groups differs. For example, Treatment 2 has been compared with usual care a number of times, whereas Treatment 1 has only been compared once with usual care.

NMA Assumptions

There are a number of assumptions to be met when conducting NMA.

Network Connectivity

For a treatment to be considered in NMA, it must be connected to the evidence network. In essence, for Treatment 1 to be evaluated, there must be at least one comparison study between it and some other node in the network (e.g., usual care).

Homogeneity

NMA assumes that the included studies are sufficiently homogenous in terms of the condition being studied, the included participants, and the definition of

Figure 2 (a) Shows Treatments 1, 2, and 3 in a Closed Loop; (b) Illustrates a Star-Shaped Network, Where Four Treatments Were Compared With a Usual Care Group but not With Each Other

active and control interventions. The selection of trials to examine the NMA should be based on rigorous criteria, and common sources of heterogeneity, such as clinical–demographic factors, methodological aspects, treatment content and process, control group content and process, and statistical analytical methods, must be considered for each study included. If the intervention effect is heterogenous, then a fixed effects model can be applied; if the effects are heterogenous, then a random effects model is used.

Transitivity and Consistency

Transitivity relates to the assumption that an indirect comparison between two treatments in the network is a valid estimate of the direct comparison between these two treatments. This can be formally statistically tested when we have both direct and indirect evidence in the network—that is, studies that directly compare the treatments and also studies that compare the treatments to a common other treatment (e.g., usual care). Consistency is the statistical measure of transitivity; it can be examined at the level of the entire network or can be assessed for certain pathways in the network. Estimates in an NMA are consistent when the indirect evidence and the direct evidence agree. When such direct comparisons have not been conducted, then they cannot be tested directly statistically. However, NMA requires some assessment of

transitivity, as a violation of this assumption leads to biased indirect comparison estimates, which result in overall biased NMA estimates.

Transitivity can be examined by assessing variables that might influence the effect of intervention (*effect modifiers*) to see how present they are in each of the included studies. Effect modifiers are clinical and methodological features of the included studies that could affect the size of effect: the strength of intervention effect may be influenced by the characteristics of the participants, the measurement process (e.g., self-report survey, clinical interview) and timing of assessments, the intervention duration, mode of delivery, training levels of the interventionists, fidelity to the treatment, contents of the control condition, and setting, among others. For NMA to produce valid results, the distribution of effect modifiers should be similar across studies to increase the plausibility of reliable findings from an indirect comparison. For example, if the sample in Treatment 1 versus usual care only includes those with severe depression, whereas the sample in Treatment 2 versus usual care includes those with mild symptoms of depression, then differences in sample might modify the effect of the intervention, which would violate the assumption of transitivity for the indirect comparison of Treatment A versus Treatment B.

Estimates of the effect sizes from NMA can be confounded by the uneven distribution of effect modifiers across the evidence network. If there is variation in

effect modifiers across the trials in the network, meta-regression can be used to perform the covariate adjustment, subgroup analyses can be conducted, or indeed, it may not be possible to conduct the NMA.

Study Quality

Critical appraisal of the methodological quality of randomized controlled trials in an NMA is important because studies at high risk of bias can lead to violations of the homogeneity, transitivity, and consistency assumptions. Assessing the risk of bias for each included study needs to be conducted to inform the data synthesis. In addition to the risk of bias arising from the individual studies, NMA should also examine the risk of bias across the included studies that may affect the cumulative evidence (e.g., publication bias, selective reporting within studies). In the presence of heterogeneity or inconsistency in the network, poor quality of the studies, or only a small amount of data available, NMA results need to be interpreted with caution.

Sample Size

Studies with small sample sizes may provide biased estimates, which can propagate through the evidence network and affect different parts of the network in different ways. Consequently, NMA is not advisable when evidence is only available from small and underpowered trials.

Conducting and Reporting an NMA

NMA can be conducted for most types of effect size estimates, including continuous and dichotomous outcomes, and event rates (e.g., mean difference, odds ratio, relative risk). The treatments of interest form a connected network of comparisons, which facilitates comparison of the relative effects of each treatment with estimates of their uncertainty (e.g., 95% CIs). NMA can be conducted using either a frequentist or a Bayesian approach. Frequentist analyses calculate the probability that the observed data would have occurred under their sampling distribution for hypothesized values of the parameters. A Bayesian approach requires the prior probability distribution to be specified for the parameter of interest (e.g., treatment effect). This distribution provides the initial estimate of the range and probability of plausible values for the treatment effect. Bayesian NMA then provides the posterior distribution that describes the new range and probability of plausible values for the treatment effect, on which statistical inferences are based.

Regardless of the framework used, the fit of the model to the data should be examined. Networks that have both direct and indirect evidence contributing to estimates should have the assumption of consistency statistically assessed by comparing the results obtained using the direct evidence alone with the results obtained using the indirect evidence alone to see whether the estimates are significantly different. Methods that assess consistency in the whole network are also available and are preferred when networks are large. If inconsistencies are found, then the characteristics of the studies should be reexamined and adjustment for effect modifiers (e.g., covariates or risk of bias) can be applied. If there are a small number of studies comparing the exact same treatments, then this can lead to limited network connectivity in NMA, and therefore, low statistical power, low network connectivity, and large confidence intervals for estimated effect sizes make interpretation difficult.

NMA can currently be conducted in commercial (e.g., STATA, SAS) and free open access software packages (e.g., R, Python). The PRISMA extension for NMA provides guidance on reporting the results in a clear and comprehensive manner. It has developed a checklist that authors can use for tracking inclusion of key elements in reports of network meta-analyses.

NETWORK SAMPLING

Network sampling designs select subsets of the nodes and relationships in a network for observation and study. Some network samples are drawn in order to estimate properties of a network—like density, centralization, or segmentation—or parameters of stochastic

network models. Other network samples identify pools of subjects for survey studies about characteristics of a population of nodes. This entry describes some major network sampling designs employed in these ways and concludes with considerations for researchers when making inferences from network samples.

All network sampling designs select subsets of both the nodes and the relationships that comprise a network. Some designs explicitly sample nodes from a list or other sampling frame, and then observe them and the relationships in which they are involved. Others start by sampling relationships, then studying them together with the nodes they connect. Still others instead begin with an initial set of nodes and use referrals from that initial set to others in constructing a sample.

Node-Based Designs

One approach to sampling from a network begins by using some probability scheme to select a set of nodes from a sampling frame listing all nodes in the network of interest. “Induced subgraph” sampling then obtains data on relationships among all pairs of the sampled nodes. A “sampling of stars” or “egocentric network sampling” design instead measures the relationships between the sampled nodes and all nodes (sampled or unsampled) in the population. Subsequent data collection may or may not specifically identify the “alter” nodes related to a sampled node.

For a given number of sampled nodes, the egocentric design provides more information. Consider an undirected one-mode network in a school with 1,000 students, and hence $(1,000)(999)/2 = 499,500$ dyads (potential relationships). For a sample of 100 students (e.g., from school enrollment records), the induced subgraph design would collect data on $(100)(99)/2 = 4,950$ dyads. Egocentric network sampling would yield, in addition, information about the $100(900) = 90,000$ dyads consisting of sampled and unsampled students.

Relationship-Based Designs

If a list of dyadic relationships (e.g., alliances between companies or international agreements) exists, one can sample from a one-mode network by selecting relationships from it. Those nodes involved in the sampled relationships would thereby be chosen. Such a design tends to select higher degree nodes—those involved in more relationships—requiring that suitable weights be employed.

Hypernetwork sampling extends this design to sampling from a two-mode network that depicts relationships between entities of two distinct types, say

individuals and groups. If a sampling frame is available for one type of entity (say groups), a sample of elements may be drawn from it. Entities of the other type (individuals) affiliated with the sampled elements (groups) will thereby be selected, with probability proportional to their degree (number of group affiliations).

Link-Tracing Designs

Link-tracing designs develop a sample from a population by following connections between nodes. Several such sampling schemes exist, known by names including multiplicity sampling, random walk sampling, respondent-driven sampling, snowball sampling, and others. All of them begin by selecting—and collecting data from—one or more “seed” nodes; these data include information about links between the seeds and other nodes in the population. They then select one or more nodes to which each seed is related and add them to the sample. Such tracing may occur only once or be repeated by tracing links from the added nodes to still others, possibly several times. Link-tracing methods are often used when no listing of network nodes is available.

Link-tracing designs vary in several respects. Some sample seed nodes randomly, while others choose them on a purposive or convenience basis. The number of waves of tracing can differ, as can the number of referrals from each seed (or subsequent subject, in multi-wave variants) that are added to the sample. In some designs, investigators decide which links to trace; others engage subjects in selecting them.

Reflecting the well-known phenomenon of homophily—the tendency for social ties to connect similar actors—seeds and those they refer tend to resemble one another. This dependence weakens as successive waves increase the degree of separation between the seeds and newly added subjects. After a sufficient number of waves, subjects from later waves can resemble a random sample of all nodes in a network, even if the seed nodes are not chosen probabilistically.

Link-tracing designs sample interconnected sequences of nodes (“walks”) within a network, thereby yielding insights into patterns of network connectivity. They can be used successfully to estimate stochastic network models. Among their principal applications, however, is to identify samples of subjects from difficult-to-study populations that are unlisted (e.g., bluegrass musicians in a city) or “hidden” because of a stigmatized identity or tenuous social standing (e.g., undocumented immigrants, sex workers, or intravenous drug users). If members of such a population are aware of and connected to one another—and willing to

refer others in it—they can be sampled via link-tracing methods.

Respondent-driven sampling, a variant of link-tracing, is widely and successfully used in studying hidden populations. It typically begins by selecting diverse seeds known to be within the population of interest, based on either advance fieldwork or convenience. Seed nodes receive incentives for study participation, and may earn additional compensation as recruiters, by distributing coupons inviting their contacts to enroll. A contact may, in turn, opt to be a study subject by presenting a coupon to investigators, who verify eligibility; after participating, the contacts may recruit still others. In this design, investigators have only partial control over the links traced.

Inference from Network Samples

Estimating population statistics and making inferences from network samples is a complex undertaking and a very active area of methodological research. For many network statistics of interest, sample analogs of population-level formulas do not yield unbiased estimates of those statistics. Inclusion probabilities (and hence weights) for nodes and/or relationships may be unavailable or difficult to ascertain. Sampling variances are well-understood for some, but by no means all, network statistics and sampling designs. Approaches to inference that rest on, or are assisted by, stochastic network models have seen some success. Researchers seeking to make inferences based on network samples should consider carefully both the network statistics involved and the sampling design used to select nodes and relationships from the population network.

NETWORK SIZE

In network analysis, network size refers to the total number of nodes in a network. Depending on the network, nodes represent different types of interacting components such as individuals in a social network, websites on the World Wide Web, neurons in a neural network, or species in a food web. The real-world networks that have been studied using network analysis vary substantially in size, ranging from less than 100 to several hundred thousand nodes. Social networks and food webs are among the smallest networks, while transportation networks and the World Wide Web are some of the largest. The sections that follow give a brief introduction to the role of size in network analysis, including network properties related to size and how size should be considered in the context of sampling and analysis.

It should be noted that the term *network size* has been used to refer to other network properties such as the total number of links between nodes in a network, the total number of potential links (if every node in a network interacts with all other nodes), or, in the case of personal networks, ego network size. Although these measures may be correlated with network size as commonly used, and defined here, they should not be confused.

Network Properties Related to Size

Many of the underlying properties of real-world networks have been shown to be related to network size and these properties are shared across many different types of networks. As a network grows in size, the number of possible links between nodes grows quickly, since each new node will have more potential interaction partners than the previous one. However, the number of links that are realized does not grow at the same rate. Thus, most networks grow sparser in their number of realized links with an increasing number of nodes. It has also been suggested that new nodes entering the network preferentially attach to the most connected nodes, which results in a type of growth in which the “rich get richer.” This means that a few nodes will have a disproportionately large number of links while most nodes have very few links. In networks with this so-called “scale-free” property, highly connected nodes function as hubs in the network and the number of links a hub has can grow polynomially with network size. The hubs provide shortcuts through the network so the shortest distance (measured as number of links traveled) between two randomly chosen nodes remains relatively short, even in large networks. Since most

nodes have few links, the “scale-free” property also makes networks robust to the random removal of nodes. When a node is lost from the network, this can have consequences for other nodes it was linked to, potentially starting a cascading loss of nodes. When most nodes have few links, however, the network is generally robust to losing these, and this robustness increases with network size. How much network properties vary with size, and how closely networks follow the aforementioned organizing principles, remains under debate and can vary between different types of networks.

Correcting for Size in Analyses

Network structure is quantified by a range of different metrics (such as path length and centralization), many of which are sensitive to differences in network size (and density) even when the underlying structure is similar. Thus, when comparing networks that vary in size, it can be challenging to distinguish the effect of size from other structural differences of interest. Different approaches have been proposed to account for size effects, including, for example, using metrics normalized by network size, comparing with baseline models, or simply using metrics that are less sensitive to size effects.

Sampling Networks of Different Sizes

It is also important to consider variations in network size when sampling networks. In the same type of system, the larger the network, the higher the sampling effort needed (measured in number of sampling unit) to observe all nodes and their links. Undersampling is a widespread, and often overlooked, problem in network analysis and almost all sampled networks only represent a subset of the full, real-world network. How well this subset represents the structure of the full network depends on sampling method, sampling effort, and the characteristics of the system, including size. It may be relatively easy to register, or observe, many nodes in a network, but it usually requires much higher effort to observe the links between nodes, especially when their interaction is limited in time. This means that when a network is severely undersampled, only the most common nodes and links may be observed, whereas the rare ones are likely to be missed. This can result in sampling bias when network structure is quantified.

Since large networks are more likely to suffer from undersampling, it is difficult to disentangle the combined effects of undersampling and network size on network structural metrics. This can result in sampling effects being misinterpreted as relevant responses when

comparing networks of different sizes. A range of methods have been proposed to overcome sampling bias, such as estimating link probabilities, replacing missing data with imputation methods, or identifying and using metrics that are relatively robust to undersampling in a given system. These methods do not always perform well, and understanding the combined effects of undersampling and network size remains a challenge in network analysis. It is, therefore, important to be aware of the limitations missing data introduce to our understanding and interpretation of metric variation, especially when comparing networks that vary in size.

NETWORK STRUCTURE

Network structure refers to a general system, network, or pattern of relationships that can be derived from the observable behavior of animate and inanimate actors or objects in a given population. Structure is usually understood as the arrangement of parts or elements of some complexity tied together by relations. The study of these relations is the subject of network theory.

A network consists of nodes and links that form dyads, triads, groups, or a system of interconnected animate (actors) and inanimate objects, based on the specific types of relationships between them. In a dyad, ties come together, through the type of relation, to create a system of interdependence. Triads are fundamental network structures. There are 16 types of triads in a directed network in which balanced relationships or

structural holes can be analyzed. This entry further defines network structure and then discusses the theoretical concepts behind it, basic types of networks in terms of their topology, and the measurement of network topology.

A network is dynamic by nature. Within network structure, nodes and relations are established, maintained, or broken (deleted), determining similarity between attitudes and behaviors. There is a shift from individual-level analysis to relational and systemic research.

Network structure and networks are an excellent way of presenting phenomena and objects from the perspective of the network of relations, interactions, and interdependence between them. Animate objects (e.g., human entities, organizations, animals), inanimate objects (e.g., things, artifacts), or contemporary epidemiological phenomena are mutually dependent on each other, creating an extensive, complex, and dynamic network structure. Many complex systems have a network structure. The most popular of them are the Internet, World Wide Web, and the citation network. Contemporary realities have driven researchers to focus on understanding the structure of the network of contacts during epidemics, which has a decisive impact on the dynamics of the spread of diseases. Determining this structure allows effective interventions to control and prevent epidemics. Standard research and social and behavioral methods pay attention to the attributes and characteristics of individual actors, which are studied independently of each other. Contemporary research in social or natural sciences, in which networks play a key role, focuses on the structure of the relations that exist between entities or objects.

Theoretical Concepts

In social sciences, network theory includes two popular concepts: the strength of weak ties, which can be considered to be within the framework of labor market theory, and structural holes, which are included in the sphere of competition theory. Within these two concepts, it is crucial to clarify the relationship between network structure and performance based on the position of the nodes in the network. According to Mark Granovetter, within an American job search context, the stronger the ties are between a couple of people in a given community, the greater the chances are of weaker ties with third parties (bridging ties) as a potential source of new information and knowledge.

In turn, the term *structural holes* refers to a pattern of relationships in at least two unrelated social networks, where an actor is associated with many other networks that have no connection with each other.

Such structural properties of the network give an actor the chance to receive nonredundant information, which favors innovation. These theoretical constructs aim to capture the network's structural features and study their impact on network participants, patterns of network creation, and change.

Complex Network Topology

The structure of the network as a whole is called *network topology*. There are many network topologies and among the most popular are small-world networks and scale-free networks, the properties and expected behavior of which differ.

In a small-world network, it has been found that a small number of relations between two random entities occur regularly in different systems where there are short paths, and its theoretical model is small in diameter. Moreover, it has a relatively high clustering factor. Research into the characteristics of the small-world network structure has been conducted in the context of college classes and the implications of the spread of an epidemic at universities or hospital work organization.

Scale-free networks are the result of the dynamic emergence of networks and the preferential (not random) relation of subsequent nodes that are more likely to connect to those with a greater number of relations (hubs). Scale-free networks are immune to random events that may affect their structure, provided that the events are not aimed at central nodes. Examples of research on scale-free networks are modeling the belief system and the spread of biological and computer viruses.

Network Structure Measures

Network structure can be studied and measured with social and dynamic network analysis, which allows the study of network topology, network behavior, and evolution, as well as an understanding of why networks are structured the way they are. This analysis reveals the privileges of some nodes and the advantages of some types of networks over others. The basic measures at the whole network level are density and centralization.

Density measures the actual number of links between nodes in relation to all links that exist. This allows the assessment of the degree of networking of the studied system or population. Centralization refers to the overall integration or coherence of the network. It determines the relative dominance of a single node over others in the network and then the entire network is characterized by a centralized structure in which there are many links around one node. Conversely, a

network structure takes a decentralized form. Both the dense and centralized network structures have inevitable positive and negative consequences. Network structures, and positions in the network, create both opportunities and limitations depending on the functional value of the relationships studied. The network's overall efficiency can be assessed through the prism of possible fragmentation and the redundancy of nodes or relations.

NETWORK VISUALIZATION

Network visualization is a subdiscipline of network analysis whose goal is to display the units of study (nodes) and the connections between them (edges). Network data are very common in the social and health sciences; examples include social networks comprising people and their relationships and comorbidity networks describing co-occurrences of conditions in a population. Network visualization is a crucial part of network analysis that allows the researcher to see the complex structure inherent to network data. This entry discusses the different types of network visualizations, their individual advantages and disadvantages, and some commonly used tools available for creating network visualizations.

Node-Link Diagrams

Node-link diagrams are the most common way to visualize network data. The study and formation of

Figure 1 A Simple Example of a Node-Link Diagram for a Social Network of 10 Individuals, Where Nodes in the Network Are Represented With Circles and Relationships Between the Nodes Are Lines

Source: Wikimedia Commons (2006): <https://commons.wikimedia.org/wiki/File:Social-network.png> (public domain).

node-link diagrams forms a subfield of mathematics and computer science known as *graph drawing*.

Definition

In a node-link diagram like the example shown in Figure 1, there are two visual objects: points and lines. The points represent the nodes, also called *vertices*, in the network. The nodes in a network are the individual units of study. The lines in a node-link diagram represent the edges, also called *ties* or *links*, which represent relationships or other connections between the nodes. If there is an edge between two nodes in a network, it is represented by a line connecting the two points. For directed networks, where the edge is defined as coming out of one node and into another, the edges have arrows on them to indicate the direction of the tie.

Node-link diagrams are typically drawn in two dimensions, though some software tools for network visualization will show the network in three dimensions. With the exception of spatial networks, in which the nodes have meaningful physical locations, the locations of points in a node-link diagram do not convey any meaning about the underlying network data.

A node in Figure 1 is represented by a circle, which is usually the default shape for a node in a node-link diagram. The nodes can be any shape, and often, text representing the node label is used instead of a geometric shape. In addition, the visual properties of the points and lines, such as size, shape, and color, can vary according to underlying node and edge information. In a social network, for example, the size of a point could represent a person's age and the shape or color can vary according to the person's gender. The lines can also show edge information: for example, solid lines for

family members and dotted lines for friends in a social network.

To construct a node-link diagram, the points are placed in 2D space according to one of several methods, then the edges are drawn as lines connecting the points.

Node Placement

There are many different methods to place the points in 2D space. Because the positions of the points typically have no meaning, the method of node placement is an important choice to make when constructing a node-link diagram.

There are many algorithms that can be used to place nodes. When using an algorithm, the points are first assigned arbitrary positions in 2D space and then are adjusted by the algorithm until some stopping criterion is achieved. Many common algorithms treat the nodes as particles and the edges as physical ties connecting the particles and then use principles from physics to adjust the placement of the points until an equilibrium state is achieved. These types of algorithms are called *force-based layouts*, and some examples include the Kamada–Kawai and Fruchterman–Reingold algorithms.

Other node placement methods include spectral layouts, arc diagrams, and circle layouts. Spectral layouts use mathematical properties of the network's adjacency matrix, such as eigenvalues, to place the nodes in 2D space. Arc diagrams display the nodes on a single line, and arcs drawn between points to represent edges. Typically, arc diagrams aim to minimize the crossing of the edges. In circle layouts, the points are drawn in a circle, usually at uniform intervals, and groups of points that are more densely connected are placed as close as possible, while edges connecting the nodes are drawn inside of the circle.

There are many other methods for placing the nodes, and researchers should consult the manual for their software of choice for a complete list. Each of the different node placement methods has its own unique set of advantages and disadvantages. Often there is no one best method to choose, and one's choice depends on the type of network data to be visualized. Researchers should rely on best practices in their field for guidance.

Advantages

The primary advantage of the node-link diagram is that structural elements, such as clusters and node centrality, are easy to identify. In addition, the node-link diagram is the best way to visualize paths connecting

two nodes. Node-link diagrams are node-centric, so it is easy to visually communicate information about the nodes.

Disadvantages

For large and densely connected networks, the node-link diagram is often not a very useful visualization. A very large node-link diagram will frequently resemble a *hairball* of points and lines. However, these large diagrams can be simplified by visualizing connections between clusters of nodes instead of individual connections between nodes.

Adjacency Matrix Visualizations

Adjacency matrix visualizations are an alternative to node-link diagrams, which assign the edges grid spaces in a pictorial matrix.

Definition

In an adjacency matrix visualization like the one shown in Figure 2, the nodes are arranged in rows and columns to create a square grid, and an edge between two nodes is represented by a filled-in square at the intersection of the two nodes in the grid. In an adjacency matrix visualization, all possible edges between any two nodes in a network are visible, but only the existing nodes are filled in. For an undirected network, the adjacency matrix is symmetrical and so is the adjacency matrix visualization. In the undirected case, each edge in the network is drawn twice, and to avoid this overrepresentation, sometimes only the lower (or upper) triangle of the adjacency matrix is shown. With the exception of bipartite networks, where there are two separate types of nodes, the order of the nodes in the rows should be the same as the order of the nodes in the columns, as they are in the adjacency matrix. The ordering can be arbitrary, perhaps by label or ID number, or an algorithm can order the nodes according to data structures. The color or transparency of the squares can also represent edge variables, such as weights in a weighted network.

Ordering

Without a careful ordering of the nodes in the adjacency matrix, an adjacency matrix visualization will not be very informative. There are many ways to construct an ordering, also called a *seriation*, all of which aim to convey underlying structural properties of the data. The seriation methods often use operations on the adjacency matrix or other data matrices to perform

Figure 2 An Adjacency Matrix Visualization for a Sparse Undirected Network With 24 Nodes and 36 Edges

the ordering. Computing eigenvalues, conducting hierarchical clustering, or performing a principal components analysis are all common methods to order the nodes in a matrix visualization.

Advantages

The adjacency matrix visualization is better for dense networks than the node-link diagram because the ordering of the rows and columns creates a structure

that is easier to perceive than in a *hairball* node-link diagram. Because this visualization type emphasizes edges, it is optimal for communicating edge information, such as weight.

Disadvantages

For undirected networks, the number of edges drawn is twice the number of edges in the network, which can be misleading. This method, unlike the node-link diagram, does not clearly show paths between nodes. And because edges are emphasized, node properties are difficult or impossible to display.

Visualizing Special Types of Networks

This section discusses two special types of networks—bipartite networks and trees—and how they can be visualized.

Bipartite Networks

Bipartite networks are a class of networks in which there are two types, or *modes*, of nodes, and edges can only exist between two nodes of different types. For example, consider a social network where one set of nodes represents scientists and another set represents professional societies. In this bipartite network example, an edge exists between a scientist and a society if the scientist belongs to the professional society. In a bipartite network visualization, a node-link diagram is typically used, in which the two node classes are represented with different colors or shading, shapes, and/or labels, and the groups of nodes are drawn opposite or on top of one another. So, all nodes of one type are drawn near each other, and there is clear visual separation between the two groups of nodes.

Visualizing both types of nodes in a bipartite network can often result in a diagram that is cluttered and difficult to interpret, so the *network projection* on one set of nodes is shown instead. The resulting network contains only one type of node, and edges connect two nodes if they are connected to one or more common nodes of the other type. In the scientists example, the network projection on the set of scientists would result in a network with edges between two scientists if they belong to one or more of the same professional societies. The edges in a bipartite network projection are often weighted to represent the number of connections the two nodes have in common. The network projection can then be visualized with a node-link diagram or adjacency matrix visualization.

Trees

A tree is a type of network in which there is only one possible path connecting any two nodes. Trees are often rooted and have a hierarchical structure, such as in family trees and phylogenetic trees. Trees are extremely common data structures in the biological and social sciences, and a lot of research has been dedicated to tree visualization. A tree visualization is called a tree diagram, and there are hundreds of ways to draw a tree diagram, many of which are variations on the node-link diagram and adjacency matrix visualizations discussed here.

Network Visualization Software

The following is a sample of available software packages for network visualization. All URLs are active as of May 2021.

- Gephi: a free, open source software program for visualizing graphs and network data. Available for download at gephi.org.
- Graphviz: a free, open source software program for network visualization. Available for download at graphviz.org.
- For R users, there are many R packages available for download from the Comprehensive R Archive Network, including *statnet*, *ggraph*, *ggnetwork*, and *igraph*.
- For Python users, available libraries for network visualization include *NetworkX* and *graph-tool* available at networkx.github.io and graph-tool.skewed.de, respectively.

This list is meant to serve as a starting point and should not be considered comprehensive or complete.

NEURAL NETWORKS

Neural networks are a classification machine learning model. Neural networks are becoming increasingly popular for identifying trends within data because neural networks can be highly individualized. To do this, neural networks accept input from data features and pass these feature values through the layers of nodes until classifications are returned as output. Neural network algorithms use activation and loss functions to allow the model to better reflect the complexity of the data and to optimize model performance, respectively. Using a running example, this entry discusses the layers, functions, and phases of neural networks, as well as other relevant considerations.

Running Example

Given the abstract nature of neural networks, a running example will be used to demonstrate concepts more concretely. Consider a data set containing information about books with variables for the number of pages in the book, the average number of words per page, the reading level, and a binary rating of whether an individual found this book interesting. Figure 1 presents a neural network for these data.

Terminology

Neural networks use much of the same terminology as machine learning. Each data point in the data set is called a *case*. In the current example, each book is a case. The variables within each case are called *features*. For example, the number of pages would be a feature of each case.

Neural networks comprise layers (e.g., input, hidden, output), which consist of nodes. Hidden layers are optional, although most neural networks include at least one hidden layer, because neural networks are essentially regression models without a hidden layer. For example, a neural network with no hidden layer, a single node in the output layer, and a sigmoid activation function make up a logistic regression model.

Neural network layers are often fully interconnected, meaning the nodes at any given level are connected to all of the nodes in adjacent layers although there are no connections between nodes at the same layer. The connections between nodes are weighted,

Figure 1 Example of a Neural Network

and the connection weights are allowed to vary within the neural network.

Layers

There are three types of layers in neural networks: the input layer, the hidden layer or layers, and the output layer. The input layer receives feature values from cases as input. The hidden layers process the information received from the case features. The output layer produces the model classifications for each case.

Input Layer

The input layer contains one node for each of the features, meaning each node is designed to receive the values from a specific feature. As shown in Figure 1, the input layer has three nodes including a node for the number of pages, a node for the average number of words per page, and a node for the reading level.

Hidden Layer

The layers between the input and output layer in a neural network are called *hidden layers*. Any number of hidden layers can be included in a neural network, although most neural networks use three or fewer hidden layers to limit the computational complexity of the neural network.

Hidden layers can also include any number of nodes, and the number of nodes can vary across the hidden layers. There is no rule for choosing the number of nodes to include in each hidden layer. In Figure 1, the neural network includes a single hidden layer containing four nodes.

Hidden layers can also include a bias node. The bias node increases the flexibility of the neural network by adding a value to the sum of the values inputted into each hidden layer node. Bias nodes can be treated as a prespecified constant or as a parameter that can be adjusted to optimize the model. The neural network in Figure 1 includes a bias node with a prespecified value of one. Note, however, the node connections between the bias node and the nodes in the hidden layer were omitted due to space constraints.

Output Layer

The output layer produces the classifications. Consequently, the number of nodes in the output layer is related to the number of classification categories. For binary classifications, a single node can be used, since this node indicates the probability of classification. In the running example, the output from the output layer would be the probability of the individual finding the

book interesting, and one minus the probability of the individual finding the book interesting equals the probability of the individual not finding the book interesting.

For nonbinary classifications, the number of nodes in the output layer is equal to the number of classification categories. If the running example were modified such that the possible classifications were “Interesting,” “Neutral,” and “Not interesting,” the output layer would include three nodes with one node for each possible classification.

Rules can be applied to the output from the output layer to generate model classifications. For example, with binary classifications, output values greater than or equal to .50 could indicate one classification (e.g., “Interesting”) and output values less than .50 could indicate the other classification (e.g., “Not interesting”). Similarly, with nonbinary classifications, the node with the greatest output value could indicate the classification.

Functions

Neural network algorithms use activation and loss functions to construct the model that best reflects the observed data. Activation functions transform the values at each node to model both linear and nonlinear trends in the data. Loss functions summarize how accurately the model conformed to the data.

Activation Functions

Activation functions, which are also called *threshold* or *transfer functions*, transform the sum of the values input into nodes in the hidden and output layers. The same activation functions are applied to each node within a layer, but there may be different activation functions applied at different layers. For example, in Figure 1, a sigmoid activation function might be applied at the hidden layer, while a different activation function might be applied at the output layer.

The choice of activation function depends on the model and data characteristics (e.g., number of nodes, type of classification, scale of the data). For example, the softmax activation function is derived from the sigmoid activation function, but the softmax is better suited for nonbinary classifications whereas the sigmoid activation function is better suited for binary classifications.

Loss Functions

Loss functions produce a numerical summary of the consistency between the model classifications and the

true classifications. Neural network algorithms seek to optimize the loss function.

To give a brief example of how a loss function works using the running example, the loss function compares the output from the output layer (e.g., .80, which suggests there is an 80% probability of finding the book interesting) with the true classification for the book (e.g., Interesting). Recoding “Interesting” as 1, the goal of the neural network algorithm is to produce a probability estimate for this case that is as close to 1 as possible. The loss function compares the difference between .8 and 1 for this case and would perform a similar comparison for all other cases. Neural network algorithms attempt to find a model that minimizes the difference between the probabilities generated in the output layer and the true classifications across the cases used to train the model. Of note, this example is a simplification of how loss functions work in practice. Specific loss functions will transform the difference between the outputs and the true classifications before optimizing the difference between the outputs and the true classifications.

Phases

Neural network algorithms strive to find the optimal set of node connection weights and node bias values, when applicable. To do this, neural network algorithms use a forward and backward phase. The forward phase passes the feature values through the neural network. The backward phase, which is also called *backpropagation*, compares the model classification with the true classification, identifies sources of error in the model classifications, and adjusts the node connection weights, and bias node values when applicable, to optimize the classifications. Neural network algorithms perform the forward and backward phases iteratively to identify the best performing model.

Forward Phase

The forward phase accepts feature values into the input layer and passes these values to the next layer by multiplying the values of the input layer by the node connection weights. At the next layer, the products of the previous node values and the connection weights are summed along with the bias node value, if applicable. This sum is then input into the activation function, and the output of the activation function will then be passed along to the next layer by multiplying the activation function output with the connection weight. This process repeats at each layer until classifications are produced at the output layer.

Using the neural network presented in Figure 1, consider a book with 25 pages, an average of 10 words per page, and a reading level of 1.0 (i.e., a first-grade reading level). These feature values are passed to the input layer, where the node for the number of pages receives 25, the node for the number of words per page receives 10, and the node for the reading level receives 1.0. The nodes in the input level then pass their values to the nodes in the hidden layer by multiplying the input data by the connection weights. Taking Node 1 in the hidden layer as an example, Node 1 receives three values: $25 \times 0.04 = 1.0$, $10 \times 0.08 = 0.8$, and $1.0 \times 0.47 = 0.47$. These three values sum to 2.27. Because a bias node with a prespecified value of 1 was included in this hidden layer, $2.27 + 1 = 3.27$ is input into the activation function. If a sigmoid function were applied to the hidden layer, the output of the activation function would be

$$\frac{1}{1 + e^{3.27}} \approx 0.03661.$$

This process occurs simultaneously at each node in the hidden layer, and the entire process would be repeated at the output layer. Classifications could be made using a rule specifying that output from the output layer greater than or equal to .50 indicates the individual would find this book interesting and output less than .50 indicates the individual would not find this book interesting.

Backward Phase

The backward phase uses the loss function to compare the output values for each node in the output layer and the true classification across all cases. The backward phase identifies how the connection weights at each layer of the model, and if applicable the bias node values, should be adjusted to improve the consistency between the output values for each node in the output layer and the true classifications. For truly interesting books in the running example, the connection weights would be adjusted to increase the output value of these cases. Conversely, for truly uninteresting books, the connection weights would be adjusted to decrease the output value of these cases. The value of the bias node in the running example would not be adjusted in this example since it is prespecified.

Performance Evaluation

The performance of neural networks can be evaluated by estimating the classification accuracy of the predictions. A confusion matrix is a 2×2 matrix containing

the frequency of true positives, true negatives, false positives, and false negatives. For binary classifications, multiple performance estimates can be calculated based on the information contained in a confusion matrix. These performance estimates include classification accuracy (i.e., the proportion of accurate classifications), classification accuracy above chance (i.e., Cohen's kappa), classification accuracy of the cases classified as positive cases (i.e., precision), classification accuracy of the cases classified as negative cases (i.e., recall), and classification accuracy based on weighted precision and recall (i.e., F β).

Technical Considerations

Neural networks can only accommodate numeric variables, which is somewhat intuitive since the node outputs are multiplied by the connection weights. This means that categorical features with nonnumerical values must be recoded with meaningful numerical values if they are to be included in neural networks.

There is also a balance between the size of the model and the performance of neural networks. Increasing the number of nodes in the hidden layers and the number of hidden layers increases the classification accuracy of the model, yet including too many nodes or too many hidden layers may overfit the model and/or make the model computationally intractable.

NEWMAN–KEULS TEST AND TUKEY TEST

An analysis of variance (ANOVA) indicates whether several means come from the same population. Such a procedure is called an *omnibus* test, because it tests the whole set of means at once (*omnibus* means “for all” in Latin). In an ANOVA omnibus test, a significant result indicates that at least two groups differ from each other, but it does not identify the groups that differ. So an ANOVA is generally followed by an analysis whose goal is to identify the pattern of differences in the results. This analysis is often performed by evaluating all the pairs of means to decide which ones show a significant difference. In a general framework, this approach, which is called a pairwise comparison, is a specific case of an “a posteriori contrast analysis,” but it is specific enough to be studied in itself. Two of the most common methods of pairwise comparisons are the Tukey test and the Newman–Keuls test. Both tests are based on the “Studentized range” or “Student’s q.” They differ in that the Newman–Keuls test is a sequential test designed to have more power than the Tukey test.

Choosing between the Tukey and Newman–Keuls tests is not straightforward and there is no consensus on this issue. The Newman–Keuls test is most frequently used in psychology, whereas the Tukey test is most commonly used in other disciplines. An advantage of the Tukey test is to keep the level of the Type I error (i.e., finding a difference when none exists) equal to the chosen alpha level (e.g., $\alpha = .05$ or $\alpha = .01$). An additional advantage of the Tukey test is to allow the computation of confidence intervals for the differences between the means. Although the Newman–Keuls test has more power than the Tukey test, the exact value of the probability of making a Type I error of the Newman–Keuls test cannot be computed because of the sequential nature of this test. In addition, because the criterion changes for each level of the Newman–Keuls test, confidence intervals cannot be computed around the differences between means. Therefore, selecting whether to use the Tukey or Newman–Keuls test depends on whether additional power is required to detect significant differences between means.

Studentized Range and Student's q

Both the Tukey and Newman-Keuls tests use a sampling distribution derived by William Gosset (who was working for Guinness and decided to publish under the pseudonym of "Student" because of Guinness's confidentiality policy). This distribution, which is called the Studentized Range or Student's q , is similar to a t -distribution. It corresponds to the sampling distribution of the *largest* difference between two means coming from a set of A means (when $A = 2$, the q distribution corresponds to the usual Student's t).

In practice, one computes a criterion denoted q_{observed} , which evaluates the difference between the means of two groups. This criterion is computed as

$$q_{\text{observed}} = \frac{M_i - M_j}{\sqrt{MS_{\text{error}} \left(\frac{1}{S} \right)}}, \quad (1)$$

where M_i and M_j are the group means being compared, MS_{error} is the mean square error from the previously computed ANOVA (i.e., this is the mean square used for the denominator of the omnibus F ratio), and S is the number of observations per group (the groups are assumed to be of equal size).

Once the q_{observed} is computed, it is then compared with a q_{critical} value from a table of critical values (see Table 1). The value of q_{critical} depends on the α -level, the degrees of freedom $v = N - K$, where N is the total number of participants and K is the number of groups, and on a parameter R , which is the number of means being tested. For example, in a group of $K = 5$ means ordered from smallest to largest,

$$M_1 < M_2 < M_3 < M_4 < M_5$$

$R = 5$ when comparing M_5 with M_1 ; however, $R = 3$ when comparing M_3 with M_1 .

F range

Some statistics textbooks refer to a pseudo- F distribution called the " F range" or " F_{range} " rather than the Studentized q distribution. The F_{range} can be computed easily from q using the following formula:

$$F_{\text{range}} = \frac{q^2}{2}. \quad (2)$$

Tukey Test

For the Tukey test, q_{observed} (see Equation 1) is computed between any pair of means that need to be tested. Then, q_{critical} value is determined using $R = \text{total number}$

of means. The q_{critical} value is the same for all pairwise comparisons. Using the previous example, $R = 5$ for all comparisons.

Newman-Keuls Test

The Newman-Keuls test is similar to the Tukey test, except that the Newman-Keuls test is a sequential test in which q_{critical} depends on the range of each pair of means. To facilitate the exposition, we suppose that the means are ordered from the smallest to the largest. Hence, M_1 is the smallest mean and M_A is the largest mean.

The Newman-Keuls test starts exactly like the Tukey test. The largest difference between two means is selected. The range of this difference is $R = A$. A q_{observed} is computed using Equation 1, and that value is compared with the critical value, q_{critical} , in the critical values table using α , v , and R . The null hypothesis can be rejected if q_{observed} is greater than q_{critical} . If the null hypothesis cannot be rejected, then the test stops here because not rejecting the null hypothesis for the largest difference implies not rejecting the null hypothesis for any other difference.

If the null hypothesis is rejected for the largest difference, the two differences with a range of $A-1$ are examined. These means will be tested with $R = A-1$. When the null hypothesis for a given pair of means cannot be rejected, none of the differences included in that difference will be tested. If the null hypothesis is rejected, then the procedure is reiterated for a range of $A-2$ (i.e., $R = A-2$). The procedure is reiterated until all means have been tested or have been declared non-significant by implication.

It takes some experience to determine which comparisons are implied by other comparisons. Figure 1 describes the structure of implication for a set of 5 means numbered from 1 (the smallest) to 5 (the largest). The pairwise comparisons implied by another comparison are obtained by following the arrows. When the null hypothesis cannot be rejected for one pairwise comparison, then all the comparisons included in it are crossed out so that they are not tested.

Example

An example will help describe the use of the Tukey and Newman-Keuls tests and Figure 1. We will use the results of a (fictitious) replication of a classic experiment on eyewitness testimony by Elizabeth F. Loftus and John C. Palmer. This experiment tested the influence of question wording on the answers given by eyewitnesses. The authors presented a film of a

multiple-car accident to their participants. After viewing the film, participants were asked to answer several specific questions about the accident. Among the questions, one question about the speed of the car was presented in five different versions:

1. *Hit*: About how fast were the cars going when they *hit* each other?
2. *Smash*: About how fast were the cars going when they *smashed* into each other?
3. *Collide*: About how fast were the cars going when they *collided* with each other?
4. *Bump*: About how fast were the cars going when they *bumped* into each other?
5. *Contact*: About how fast were the cars going when they *contacted* each other?

In our replication we used 50 participants (10 in each group); their responses are given in Table 2.

Tukey Test

For the Tukey test, the q_{observed} values are computed between every pair of means using Equation 1. For example, taking into account that the MS_{error} from the

Figure 1 Structure of Implication of the Pairwise Comparisons When $A = 5$ for the Newman-Keuls Test

Notes: Means are numbered from 1 (the smallest) to 5 (the largest). The pairwise comparisons implied by another one are obtained by following the arrows. When the null hypothesis cannot be rejected for one pairwise comparison, then all the comparisons included in it can be crossed out to omit them from testing.

previously calculated ANOVA is 80.00, the value of q_{observed} for the difference between M_1 and M_2 (i.e., “contact” and “hit”) is equal to

Table 2 A Set of Data to Illustrate the Tukey and Newman-Keuls Tests

	<i>Experimental Group</i>				
	<i>Contact</i>	<i>Hit</i>	<i>Bump</i>	<i>Collide</i>	<i>Smash</i>
	21	23	35	44	39
	20	30	35	40	44
	26	34	52	33	51
	46	51	29	45	47
	35	20	54	45	50
	13	38	32	30	45
	41	34	30	46	39
	30	44	42	34	51
	42	41	50	49	39
	26	35	21	44	55
	M_1	M_2	M_3	M_4	M_5
M_a	30.00	35.00	38.00	41.00	46.00

Notes: $S = 10$, $MS_{\text{error}} = 80.00$

$$\begin{aligned}
 q_{\text{observed}} &= \frac{M_1 - M_2}{\sqrt{MS_{\text{error}} \left(\frac{1}{S} \right)}} \\
 &= \frac{35.00 - 30.00}{\sqrt{80.00 \left(\frac{1}{10} \right)}} \\
 &= \frac{5}{\sqrt{8}} \\
 &= 1.77.
 \end{aligned}$$

The values of q_{observed} are shown in Table 3. With Tukey's approach, each q_{observed} is declared significant at the $\alpha = .05$ level (or the $\alpha = .01$ level) if it is larger than the critical value obtained for this alpha level from the table with $R = 5$ and $v = N - K = 45$ degrees of freedom (45 is not in the table so 40 is used instead). The $q_{\text{critical}(5), \alpha = .05}$ is equal to 4.04 and the $q_{\text{critical}(5), \alpha = 0.1}$ is equal to 4.93.

When performing pairwise comparisons, it is customary to report the table of differences between means with an indication of their significance (e.g., one star meaning significant at the .05 level, and two

stars meaning significant at the .01 level). This is shown in Table 4.

Newman-Keuls Test

Note that for the Newman-Keuls test, the group means are ordered from the smallest to the largest. The test starts by evaluating the largest difference that corresponds to the difference between M_1 and M_5 (i.e., "contact" and "smash"). For $\alpha = .05$, $R = 5$ and $v = N - K = 45$ degrees of freedom, the critical value of q is 4.04 (using the v value of 40 in the table). This value is denoted as $q_{\text{critical}(5)} = 4.04$. The q_{observed} is computed from Equation 1 (see also Table 3) as

$$q_{\text{observed}} = \frac{M_5 - M_1}{\sqrt{MS_{\text{error}} \left(\frac{1}{S} \right)}} = 5.66. \quad (3)$$

Now we proceed to test the means with a range of 4, namely the differences $(M_4 - M_1)$ and $(M_5 - M_2)$. With $\alpha = .05$, $R = 4$ and 45 degrees of freedom, $q_{\text{critical}(4)} = 3.79$. Both differences are declared significant at the .05 level $q_{\text{observed}(4)} = 3.89$ in both cases. We then proceed to test the comparisons with a range of 3. The value of

Table 3 Absolute Values of q_{observed} for the Data from Table 2

<i>Experimental Group</i>					
	M_1 Contact 30	M_2 Hit 35	M_3 Bump 38	M_4 Collide 41	M_5 Smash 46
$M_1 = 30$ Contact	0	1.77 ns	2.83 ns	3.89 ns	5.66**
$M_2 = 35$ Hit		0	1.06 ns	2.12 ns	3.89 ns
$M_3 = 38$ Bump			0	1.06 ns	2.83 ns
$M_4 = 41$ Collide				0	1.77 ns
$M_5 = 46$ Smash					0

Notes: For the Tukey test, q_{observed} is significant at $\alpha = .05$ (or at the $\alpha = .01$ level) if q_{observed} is larger than $q_{\text{critical}} = 4.04$ ($q_{\text{critical}} = 4.93$).
 * $p < .05$. ** $p < .01$.

Table 4 Presentation of the Results of the Tukey Test for the Data from Table 2

<i>Experimental Group</i>					
	M_1 Contact 30	M_2 Hit 35	M_3 Bump 38	M_4 Collide 41	M_5 Smash 46
$M_1 = 30$ Contact	0	5.00 ns	8.00 ns	11.00 ns	16.00**
$M_2 = 35$ Hit		0	3.00 ns	6.00 ns	11.00 ns
$M_3 = 38$ Bump			0	3.00 ns	8.00 ns
$M_4 = 41$ Collide				0	5.00 ns
$M_5 = 46$ Smash					0

Notes: * $p < .05$. ** $p < .01$. The q_{observed} is greater than $q_{\text{critical}(5)}$ and H_0 is rejected for the largest pair.

q_{critical} is now 3.44. The differences ($M_3 - M_1$) and ($M_5 - M_3$), both with a q_{observed} of 2.83, are declared non-significant. Furthermore, the difference ($M_4 - M_2$), with a q_{observed} of 2.12, is also declared nonsignificant. Hence, the null hypothesis for these differences cannot be rejected, and all comparisons implied by these differences should be crossed out. That is, we do not test any difference with a range of $A - 3$ [i.e., ($M_2 - M_1$), ($M_3 - M_2$), ($M_4 - M_3$), and $M_5 - M_4$]. Because the comparisons with a range of 3 have already been tested and found to be nonsignificant, any comparisons with a range of 2 will consequently be declared nonsignificant as they are implied or included in the range of 3 (i.e., the test has been performed implicitly).

As for the Tukey test, the results of the Newman-Keuls tests are often presented with the values of the pairwise differences between the means and with stars indicating the significance level (see Table 5). The comparison of Table 5 and Table 4 confirms that the Newman-Keuls test is more powerful than the Tukey test.

**Figure 2** Newman-Keuls Test for the Data from a Replication of Loftus & Palmer (1974)

Note: The number below each range is the q_{observed} for that range.

NODE, RELATIONSHIP, AND NETWORK ATTRIBUTES

In research designs for studying social networks, information about the relationships that link one or more sets of nodes or actors is usually augmented with attribute data that describe individual nodes, relationships, or the network as a whole. Attribute data are often essential for addressing research questions about both the formation of social networks and the outcomes that follow from them. This entry describes the different types of attribute data used in social network studies, accompanied by examples of how such data are employed.

Node Attributes

Most network studies conducted by social scientists include data describing the nodes, often termed *actors*, connected by the relationships that make up a network. Nodal attribute data can encompass virtually any individual-level measurement; the subject matter of any given study guides the selection of attributes. Attributes can include information deemed relevant to predicting network structure or formation, including background characteristics such as an individual's age, gender, education, or race/ethnic identity, and indicators of membership or official position within an organization or association. Other actor attributes regarded as responses to network location—for example, as outcomes of social influence processes or social support provision—may also be included. Examples are behaviors such as smoking, delinquent activity, or alcohol use; achievements like academic performance or awards; and attitudes or sentiments such as happiness, life satisfaction, political orientation, or tastes for musical genres.

Visualizations of networks can use attribute values to distinguish nodes by size, color, shading, or shape. Exploration of patterns in visual renderings may suggest differences between types of actors situated in central and peripheral locations within a network, or clusters of actors that tend to share similar attribute values. Statistical analyses draw on nodal attributes when identifying types of actors that are more or less apt to be involved in relationships, such as factors predicting student popularity in school classrooms.

Many network composition measures used in ego-centric network studies are based on the average attribute values for the set of “alter” nodes that lie within a focal “ego” node's network; examples include the proportion of liberals among a node's alters or their average age. Some measures of network diversity are based, correspondingly, on variability in attribute values for those alters in an actor's egocentric network.

One-mode cross-sectional network studies examine relationships linking nodes of one type—like students or countries—on a single occasion. These would include one set of attribute values describing each node. Two-mode designs involving relationships between two types of entities, such as memberships of students in extracurricular groups, may introduce separate sets of attributes for the nodes of different types. Extracurricular groups might be distinguished by their size, gender composition, and principal activity (athletic, arts-related, service-oriented), for instance, and students by their background characteristics.

Longitudinal network studies measure relationships among the nodes in a network repeatedly at points in time. Such studies can include both time-constant attributes like gender and time-varying ones such as smoking behavior at each occasion of measurement. Longitudinal designs are better suited than cross-sectional ones to adjudicating between alternative accounts for associations between nodal attributes and relationships. Such associations might reflect influences of the alters related to an actor, for example, characteristics of one's close friends that prompt smoking cessation. They can, of course, also reflect selection processes—for instance, when an actor breaks off existing relationships and initiates new ones because she or he wants to stop smoking.

Relationship Attributes

Many network studies also include attribute data that measure characteristics of pairs of nodes or of actually observed relationships. Prominent relationship attributes are indicators of the strength or intensity of a relationship. Such data may be based on the frequency or volume of communication, on the perceived emotional closeness of a relationship, or on a tie's duration. Measures of strength may be used as weights when constructing networks in which relationships are valued, instead of the more typical binary ones including ties that are either present or absent. Network visualizations can be enhanced by letting line thicknesses correspond to tie strength.

Of special importance here are dyad-level measures that indicate whether two actors have the same (or similar) values of a node-level attribute. Examples of such relationship attributes are whether the nodes in a dyad have the same gender or race/ethnic identity, or the difference in age between a pair of actors. Similarity/difference measures like these are vital to assessing the presence and extent of homophily, that is, the disproportionate tendency for relationships to link pairs of actors who resemble one another.

Among other relationship attributes is the physical distance separating two nodes or actors. Examples of categorical relationship attributes are the setting in which a relationship first formed (e.g., family, workplace, association) and indicators of whether the maintenance of a tie involves each of several different modes of contact, including in-person, mail, telephone, and/or internet communication. Visualizations of networks can use distinct line patterns or colors to depict differences in relationship attributes like these.

Network Attributes

Many network studies are, in essence, case studies of social relationships in particular groups or settings. They often examine associations between a node's network location and its predictors or outcomes. Some study designs, however, assemble data on networks in multiple settings of a given type, such as school classrooms or social service delivery systems. These studies may seek to account for between-network differences in, for example, centralization, conflict, or average participant morale, as well as within-network phenomena.

Network-level attributes that apply to every node in a given network can help to address the latter questions. Among these are contextual measures that aggregate values of node-level attributes, such as the gender composition of a school classroom or the homogeneity of the political party affiliations of members of an association. Other network-level attributes are structural measures that reflect some property of each network as a whole, such as its density or fragmentation. Global, group-level indicators are still others: An intervention study of how educational innovations shape student networks might distinguish between classrooms that use experimental and standard teaching methods, for instance.

NODES AND RELATIONSHIPS

Social network analyses depict patterns in the connectivity of social units. A network may be represented by two interrelated sets, one consisting of the entities—known generically as *nodes*—deemed to be part of it, and the second of *relationships* that link some of those entities to others. Research designs for studying networks necessarily involve these sets. This entry defines and exemplifies these foundational elements of networks and briefly discusses some considerations involved in selecting them.

Nodes

Nodes are the units or entities within a social network. Studies sometimes use other terms—including actors, vertices, and points—to refer to nodes. Nodes are often individual persons (e.g., students, employees), but networks also may be defined on social groups like organizations, cities, or nation-states. Nodes can, as well, be documents, events, or websites—connections among which reflect human activities like citation, coauthorship, or joint participation.

One-mode designs for network analysis study nodes of a single type, for example, employees of an organization or students within a classroom or school. In two-mode designs, linkages connect two different types of nodes, for instance, authors and research articles, or nation-states and international treaty agreements. More general multimode or multilayer designs can contain additional types of nodes, each of a distinct variety.

The node sets of a network may be augmented with additional data about individual nodes. These include nodal attributes: properties such as the age or gender of an individual, or the size or sociodemographic composition of an organization. Data bases for longitudinal studies should include indicators telling whether or not a given node is part of the network at each occasion of measurement (e.g., tracking students who enter or leave a classroom during a school year).

Relationships

Relationships are the connections among pairs or groups of nodes within a network. Terms like links, ties, and lines also refer to relationships. Important respects in which relationships differ include directionality, type or content, and strength or intensity. Networks are often based on only one type of relationship but can include several types.

In one-mode designs, each relationship connects a pair or “dyad” of nodes. Some dyadic relationships are “undirected” ones—known as *edges*—that represent some commonality between nodes (e.g., being classmates or coworkers), or the existence of a channel or connection such as a kinship, alliance, or continuing collaborative tie. Other “directed” relationships have an orientation: they begin at one node in a pair and end at the other. Authority relationships in which one party can legitimately exercise control over the actions of another, flows of resources like information or advice, and sentiments such as liking or antagonism exemplify directed linkages. Directed relationships are represented by “arcs” (or “directed edges”) defined on ordered pairs of nodes. In an “asymmetric” relationship, an arc appears in one direction only, such as from node A to node B; if an arc from B to A is also present, the relationship is “mutual” or “reciprocal.”

Relationships in two-mode networks can be multiparty. They always connect two nodes of different types, for example, performers and cultural products, or students and extracurricular groups. These may induce several dyadic ties among nodes of a given type, however. A research article with four coauthors, for example, implies that each of the six pairs of contributors are collaborators. Relationships in two-mode networks are typically undirected.

In some networks, relationships are ongoing states that a dyad can enter and leave: for example, two students may initiate and later end a friendship, or two or more companies may form and subsequently conclude an alliance or joint venture. Cross-sectional studies de-emphasize the temporal aspect of these, recording the subsets of nodes that are in different states (e.g., friendships or alliances) at the occasion of measurement. Overtime studies must track whether or not each relationship is present at each time point.

Other relationships involve behaviors, including interactions like telephone or electronic mail contact, or transfers of resources like money, information, or social support. Such acts ordinarily begin and end within relatively short time intervals. Analysts often distinguish ongoing, recurrent relationships involving repeated contacts or resource flows from one-off or episodic events by aggregating the individual acts that

occur within windows of time, for instance, the number of electronic mail messages transmitted from one node to another within a week or month.

The content of relationships varies widely. Many network studies focus on ties with a positive valence, such as friendship, liking, solidarity, or cooperation. Some of these involve the provision of diverse forms of support; examples include transfers of information, help with major or minor tasks, financial assistance, and advice and counseling. Investigations of interorganizational or international networks often center on collaborative relationships such as joint ventures or treaty agreements. Ties having a negative content, like antagonism or conflict, are occasionally studied.

At a minimum, network study designs involve one relationship, but it is often important that they include two or more “types of tie” at once. Studies of work groups within organizations may, for instance, simultaneously study instrumental (advice/assistance/workflow) and socioemotional (friendship) links. A single-stranded (e.g., friendship only) relationship is said to be *uniplex*, whereas a multistranded one (e.g., both friendship and advice) is termed *multiplex*.

By itself, the set of relationships indicates only whether or not a given edge or arc is present within a network. Each element of that set may be accompanied by a weight indicative of that relationship’s intensity or strength; weights can be based on a tie’s duration or the frequency of its activation, for example. Other attribute data describing a relationship—such as its content or number of strands—may also be part of a network data base.

Selecting Nodes and Relationships

A social network analysis aspires to represent the structure of relationships via which actors or nodes affect one another—that is, the interdependencies that underlie a group’s functioning and performance, or that influence the attitudes, sentiments, or behaviors of individual nodes. This requires careful attention to criteria for establishing network boundaries—rules of inclusion for both nodes and the types of relationships that connect them—when designing studies and assembling data. Although it is difficult in practice to achieve complete closure, a network ideally will include all nodes that notably shape the group processes and outcomes of interest. Similarly, the relationships studied should be those that reflect the most pertinent sources of interdependence among those nodes.

NOMINAL SCALE

A nominal scale is a scale of measurement used to assign events or objects into discrete categories. This form of scale does not require the use of numeric values or categories ranked by class, but simply unique identifiers to label each distinct category. Often regarded as the most basic form of measurement, nominal scales are used to categorize and analyze data in many disciplines. Historically identified through the work of psychophysicist Stanley Stevens, use of this scale has shaped research design and continues to impact on current research practice. This entry presents key concepts, Stevens’s hierarchy of measurement scales, and an example demonstrating the properties of the nominal scale.

Key Concepts

The nominal scale, which is often referred to as the unordered categorical or discrete scale, is used to assign individual datum into categories. Categories in the nominal scale are mutually exclusive and collectively exhaustive. They are mutually exclusive because the same label is not assigned to different categories, and different labels are not assigned to events or objects of the same category. Categories in the nominal scale are collectively exhaustive because they encompass the full range of possible observations so that each event or object can be categorized. The nominal scale holds two additional properties. The first property is that all

categories are equal. Unlike in other scales, such as ordinal, interval, or ratio scales, categories in the nominal scale are not ranked. Each category has a unique identifier, which might or might not be numeric, which simply acts as a label to distinguish categories. The second property is that the nominal scale is invariant under any transformation or operation that preserves the relationship between individuals and their identifiers.

Some of the most common types of nominal scales used in research include sex (male/female), marital status (married or common-law/widowed/divorced/never-married), town of residence, and questions requiring binary responses (yes/no).

Stevens's Hierarchy

In the mid-1940s, Harvard psychophysicist Stanley Stevens wrote the influential article "On the Theory of Scales of Measurement," published in *Science* in 1946. In this article, Stevens described a hierarchy of measurement scales that includes nominal, ordinal, interval, and ratio scales. Based on basic empirical operations, mathematical group structure, and statistical procedures deemed permissible, this hierarchy has been used in textbooks worldwide and continues to shape statistical reasoning used to guide the design of statistical software packages today.

Under Stevens's hierarchy, the primary, and arguably only, use for nominal scales is to determine equality, that is, to determine whether the object of interest falls into the category of interest by possessing the properties identified for that category. Stevens argued that no other determinations were permissible, whereas others argued that even though other determinations were permissible, they would, in effect, be meaningless. A less argued property of the nominal scale is that it is invariant under any transformation. When taking attendance in a classroom, for example, those in attendance might be assigned 1, whereas those who are absent might be assigned 2. This nominal scale could be replaced by another nominal scale, where "1" is replaced by the label "present" and "2" is replaced by the label "absent." The transformation is considered invariant because the identity of each individual is preserved. Given the limited determinations deemed permissible, Stevens proposed a restriction on analysis for nominal scales. Only basic statistics are deemed permissible or meaningful for the nominal scale, including frequency, mode as the sole measure of central tendency, and contingency correlation. Despite much criticism during the past 50 years, statistical software

developed during the past decade has sustained the use of Stevens's terminology and permissibility in its architecture.

Example: Attendance in the Classroom

Again, attendance in the classroom can serve as an example to demonstrate some properties of the nominal scale. After taking attendance, the information has been recorded in the class list as illustrated in Table 1.

The header row denotes the names of the variable to be categorized and each row contains an individual student record. Student 001, for example, uses the school bus and is absent on the day in question. An appropriate nominal scale to categorize class attendance would involve two categories: absent or present. Note that these categories are mutually exclusive (a student cannot be both present and absent), collectively exhaustive (the categories cover all possible observations), and each is equal in value.

Table 1 Class List for Attendance on May 1

<i>Student ID</i>	<i>Arrives by School Bus</i>	<i>Attendance on May 1</i>
001	Yes	Absent
002	Yes	Absent
003	Yes	Present
004	Yes	Absent
005	Yes	Absent
006	Yes	Absent
007	Yes	Absent
008	Yes	Absent
009	Yes	Absent
010	No	Present
011	No	Present
012	No	Present
013	No	Present
014	No	Absent
015	No	Present

Table 2 Contingency Table for Attendance and Arrives by School Bus

		<i>Attendance</i>		
		<i>Absent</i>	<i>Present</i>	<i>Total</i>
Arrives by	Yes	8	1	9
school bus	No	1	5	6
Total		9	6	15

Permissible statistics for the attendance variable would include frequency, mode, and contingency correlation. Using the previously provided class list, the frequency of those present is 6 and those absent is 9. The mode, or the most common observation, is “absent.” Contingency tables could be constructed to answer questions about the population. If, for example, a contingency table was used to classify students using the two variables attendance and arrives by school bus, then Table 2 could be constructed.

The results of the Fisher’s exact test for contingency table analysis show that those who arrive by school bus were significantly more likely to be absent than those who arrive by some other means. One might then conclude that the school bus was late.

NOMOGRAMS

Nomograms are graphical representations of equations that predict medical outcomes. Nomograms use a points-based system whereby a patient accumulates points based on levels of his or her risk factors. The

cumulative points total is associated with a prediction, such as the predicted probability of treatment failure in the future. Nomograms can improve research design, and well-designed research is crucial for the creation of accurate nomograms. Nomograms are important to research design because they can help identify the characteristics of high-risk patients while highlighting which interventions are likely to have the greatest treatment effects. Nomograms have demonstrated better accuracy than both risk grouping systems and physician judgment. This improved accuracy should allow researchers to design intervention studies that have greater statistical power by targeting the enrollment of patients with the highest risk of disease. In addition, nomograms rely on well-designed studies to validate the accuracy of their predictions.

Deriving Outcome Probabilities

All medical decisions are based on the predicted probability of different outcomes. Imagine a 35-year-old patient who presents to a physician with a 6-month history of cough. A doctor in Chicago might recommend a test for asthma, which is a common cause of chronic cough. If the same patient presented to a clinic in rural Africa, the physician might be likely to test for tuberculosis. Both physicians might be making sound recommendations based on the predicted probability of disease in their locale. These physicians are making clinical decisions based on the overall probability of disease in the population. These types of decisions are better than arbitrary treatment but treat all patients the same.

A more sophisticated method for medical decision making is *risk stratification*. Physicians will frequently assign patients to different risk groups when making treatment decisions. Risk group assignment will generally provide better predicted probabilities than estimating risk according to the overall population. In the previous cough example, a variety of other factors might impact the predicted risk of tuberculosis (e.g., fever, exposure to tuberculosis, and history of tuberculosis vaccine) that physicians are trained to explore. Most risk stratification performed in clinical practice is based on rough estimates that simply order patients into levels of risk, such as high risk, medium risk, or low risk. Nomograms provide precise probability estimates that generally make more accurate assessments of risk.

A problem with risk stratification arises when continuous variables are turned into categorical variables. Physicians frequently commit dichotomized cutoffs of continuous laboratory values to memory to guide clinical decision making. For example, blood pressure

cut-offs are used to guide treatment decisions for hypertension. Imagine a new blood test called *serum marker A*. Research shows that tuberculosis patients with serum marker A levels greater than 50 are at an increased risk for dying from tuberculosis. In reality, patients with a value of 51 might have similar risks compared with patients with a value of 49. In contrast, a patient with a value of 49 would be considered to have the same low risk of a patient whose serum level of marker A is 1. Nomograms allow for predictor variables to be maintained as continuous values while allowing numerous risk factors to be considered simultaneously. In addition, more complex models can be constructed that account for interactions.

Figure 1 illustrates a hypothetical nomogram designed to predict the mortality probability for patients with tuberculosis. The directions for using the nomogram are contained in the legend. One glance at the nomogram allows the user to determine quickly which predictors have the greatest potential impact on the probability. Fever has a relatively short axis and can contribute less than 25 possible points. In contrast, whether the patient required intubation has a much greater possible impact on the predicted probability of mortality.

Nomograms like the one shown in Figure 1 are created from the coefficients obtained by the statistical model (e.g., logistic regression or Cox proportional hazards regression) and are only as precise as the paper graphics. However, the coefficients used to create the paper-based nomogram can be used to calculate the exact probability. Similarly, the coefficients can be plugged into a Microsoft Excel spreadsheet or built into a computer interface that will automatically calculate the probability based on the user inputs.

Why Are Nomograms Important to Research Design?

Nomograms provide an improved ability to identify the correct patient population for clinical studies. The statistical power in prospective studies with dichotomous clinical outcomes is derived from the number of events. (Enrolling excessive numbers of patients who do not develop the event of interest is an inefficient use of resources.) For instance, let us suppose that a new controversial medication has been developed for treating patients with tuberculosis. The medication shows promise in animal studies, but it also seems to carry a high risk of serious toxicity and even death in some individuals. Researchers might want to determine

INSTRUCTIONS: Locate the tic mark associated with the value of each predictor variable. Use a straight edge to find the corresponding points on the top axis for each variable. Calculate the total points by summing the individual points for all of the variables. Draw a vertical line from the value on the total points axis to the bottom axis in order to determine the hypothetical mortality probability from tuberculosis.

Figure 1 Hypothetical Nomogram for Predicting Mortality Risk in Tuberculosis (Tb)

whether the medication improves survival in some patients with tuberculosis. The nomogram in Figure 1 could be used to identify which patients are at highest risk of dying, are most likely to benefit from the new drug, and therefore should be enrolled in a drug trial. The nomogram could also be tested in this fashion using a randomized clinical trial design. One arm of the study could be randomized to usual care, whereas the treatment arm is randomized to use the Tb nomogram and then to receive the usual care if the risk of mortality is low or the experimental drug if the risk of mortality is high.

Validation

The estimated probability obtained from nomograms like the one in Figure 1 is generally much more accurate than rough probabilities obtained by risk stratification and should help both patients and physicians make better treatment decisions. However, nomograms are only as good as the data that were used for their creation. But, predicted probabilities can be graded (validated) on their ability to discriminate between pairs of patients who have different outcomes (discordant pairs). The grading can be performed using either a validation data set that was created with the same database used to create the prediction model (internal validation) or with external data (external validation). Ideally, a nomogram should be validated in an external database before it is widely used in heterogeneous patient populations.

A validation data set using the original data can be created either with the use of bootstrapping or by dividing the data set into random partitions. In the bootstrap method, a random patient is selected and a copy of the patient's data is added to the validation data set. The patient's record is maintained in the original data set and is available for subsequent random selection. The random selection of patients is continued until a dataset that is the same size as the original data has been formed. The model is applied (i.e., fit) to the bootstrap data and the model is graded on its ability to predict accurately the outcome of patients in either the original data (apparent accuracy) or the bootstrap sample (unbiased accuracy). Alternatively, the original data can be partitioned randomly. The model is fit to only a portion of the original data and the outcome is predicted in the remaining subset. The bootstrap method has the added benefit that the sample size used for the model fitting is not reduced.

Evaluating Model Accuracy

As mentioned previously, the models' predictions are evaluated on their ability to discriminate between pairs of discordant patients (patients who had different outcomes). The resultant evaluation is called a concordance index or c-statistic. The concordance index is simply the proportion of the time that the model accurately assigns a higher risk to the patient with the outcome. The c-statistic can vary from 0.50 (equivalent to the flip of a coin) to 1.0 (perfect discrimination). The c-statistic provides an objective method for evaluating model accuracy, but the minimum c-statistic needed to claim that a model has good accuracy depends on the specific condition and is somewhat subjective. However, models are generally not evaluated in isolation. Models can be compared head-to-head either with one another or with physician judgment. In this case, the most accurate model can generally be identified as the one with the highest concordance index.

However, to grade a model fully, it is also necessary to determine a model's calibration. Calibration is a measure of how close a model's prediction compares with the actual outcome and is frequently displayed by plotting the predicted probability (or value) versus the actual proportion with the outcome (or actual value). The concordance index is simply a "rank" test that orders patients according to risk. A model can theoretically have a great concordance index but poor calibration. For instance, a model might rank patients appropriately while significantly overestimating or underestimating the probability (or value) in all of the patients.

Conclusion

Designing efficient clinical research, especially when designing prospective studies, relies on accurate predictions of the possible outcomes. Nomograms provide an opportunity for researchers to easily identify the target population that will be predicted to have the highest incidence of events and will therefore keep the necessary sample size low. Paper-based nomograms provide an excellent medium for easily displaying risk probabilities and do not require a computer or calculator. The coefficients used to construct the nomogram can be used to create a computer-based prediction tool.

However, nomograms are only as good as the data that were used in their creation, and no nomogram can provide a perfect prediction. Ultimately, the best evaluation of a nomogram is made by validating the prediction accuracy of a nomogram on an external data set and comparing the concordance index with another prediction method that was validated using the same

data. The validation of nomograms provides another opportunity for research design. Prospective studies that collect all the predictor variables needed to calculate a specific nomogram are ideal for determining a nomogram's accuracy. In addition, more randomized controlled trials that compare nomogram-derived treatment recommendations versus standard of care are needed to promote the use of nomograms in medicine.

NONCLASSICAL EXPERIMENTER EFFECTS

In experimental designs, it is possible that an outcome is not due to manipulation of some independent variable but is actually caused by conscious or unconscious effects the experimenter has on how data are produced or processed. This could be through inadvertently measuring one group differently from another one, treating a group of people or animals that are known to receive or to have received the intervention differently compared with the control group or biasing the data otherwise. Normally, such processes happen inadvertently because of expectation and because participants sense the desired outcome in some way and hence comply or try to please the experimenter. Control procedures, such as blinding (keeping participants and/or experimenters unaware of a study's critical aspects), are designed to keep such effects at bay. Whenever the channels by which such effects are transmitted are potentially known or knowable, the effect is known as a *classical* experimenter effect. They normally operate through the known senses and very often by subliminal

perception. If an experiment is carefully designed and administered to exclude such classical channels of information transfer and such differential effects of experimenters still happen, then these effects are called *nonclassical* experimenter effects because there is no currently accepted model to understand how such effects might have occurred in the first place.

Empirical Evidence

This effect is often reported in parapsychological research. Several studies reported that parapsychological effects were found in some studies, whereas in other studies with the same experimental procedure, the effects were not shown. A well-known experiment that has shown such a nonclassical experimenter effect is one where a parapsychological researcher who had previously produced replicable results with a certain experimental setup invited a skeptical colleague into her laboratory to replicate the experiment with her. They ran the same experiment together; half of the subjects were introduced to the experimental procedures by the enthusiastic experimenter and half by the skeptical experimenter. The experimental task was to influence a participant's arousal remotely, measured by electrodermal activity, via intention only according to a random sequence. The two participants were separated from each other and housed in shielded chambers. Otherwise, all procedures were the same. Although the enthusiastic researcher could replicate the previous results, the skeptical researcher produced null results. This finding occurred even though there was no way of transferring the information in the experiment itself. This result was replicated in another study in the skeptical researcher's laboratory, where again the enthusiastic researcher could replicate the findings but the skeptic could not. There are also several studies reported where more than one experimenter interacted with the participants. If these studies are evaluated separately for each experimenter, it could be shown that some experimenters find consistently significant results, whereas others do not. These are not only exploratory findings because some of these studies could be repeated, and the experimenter effects were hypothesized.

Another experimental example is the so-called *memory-of-water effects*, where Jacques Benveniste, who was a French immunologist, had claimed that water mixed with an immunogenic substance and successively diluted in steps to a point where no original molecules were present would still have a measurable effect. Blinded experiments produced some results, sometimes replicable and sometimes not. Later, he claimed that such effects can also be digitized, recorded,

and played back via a digital medium. A definitive investigation could show that these effects only happened when one particular experimenter was present who was known to be indebted to Benveniste and wanted the experiments to work. Although a large group of observers with specialists from different disciplines were present, there was no indication how the individual in question could have potentially biased this blinded system, although such tampering, and hence a classical experimenter effect, could not be excluded.

The nonclassical experimenter effect has been shown repeatedly in parapsychological research. The source of this effect is unclear. If the idea behind parapsychology that intention can affect physical systems without direct interaction is at all sensible and worth any consideration, then there is no reason why the intention of an experimenter should be left out of an experimental system in question. Furthermore, one could argue that if the intention of an experimental participant could affect a system without direct interaction, then the intention of the experimenter could do the same. Strictly speaking, any nonclassical experimenter effect defies experimental control and calls into question the concept of experimental control.

Theoretical Considerations

When it comes to understanding such effects, traditional experimental researchers theorize that the inconsistent results are due to chance or an unknown inconsistency in how the studies are conducted, or even due to fraud; but for researchers who operate in a paradigm that accepts the possibility of parapsychological effects, this phenomenon points to a partially constructivist view of the world that is also embedded in some spiritual worldviews such as in the Buddhist, Vedanta, or other mystical concepts. Here, our mental constructs, intentions, thoughts, and wishes are not only reflections of the world or idle mental operations that might affect the world indirectly by being responsible for our future actions but also could be viewed as constituents and creators of reality itself. This is difficult to understand within the accepted scientific framework of the world. Hence, such effects and a constructivist concept of reality also point to the limits of the validity of our current worldview. For such effects to be scientifically viable concepts, researchers need to envisage a world in which mental and physical acts can interact with each other directly. Such effects make us aware of the fact that we constantly partition our world into compartments and pieces that are useful for certain purposes, for instance, for the purpose of technical control, but do not necessarily describe reality as such.

In this sense, they remind us of the constructivist basis of science and the whole scientific enterprise.

NONDIRECTIONAL HYPOTHESES

A nondirectional hypothesis is a type of alternative hypothesis used in statistical significance testing. For a research question, two rival hypotheses are formed. The *null hypothesis* states that there is no difference between the variables being compared or that any difference that does exist can be explained by chance. The *alternative hypothesis* states that an observed difference is likely to be genuine and not likely to have occurred by chance alone. Sometimes called a two-tailed test, a test of a *nondirectional alternative hypothesis* does not state the direction of the difference, it indicates only that a difference exists. In contrast, a directional alternative hypothesis specifies the direction of the tested relationship, stating that one variable is predicted to be larger or smaller than null value, but not both. Choosing a nondirectional or directional alternative hypothesis is a basic step in conducting a

significance test and should be based on the research question and prior study in the area. The designation of a study's hypotheses should be made prior to analysis of data and should not change once analysis has been implemented.

For example, in a study examining the effectiveness of a learning strategies intervention, a treatment group and a control group of students are compared. The null hypothesis states that there is no difference in mean scores between the two groups. The nondirectional alternative hypothesis states that there is a difference between the mean scores of two groups but does not specify which group is expected to be larger or smaller. In contrast, a directional alternative hypothesis might state that the mean of the treatment group will be larger than the mean of the control group. The null and the nondirectional alternative hypothesis could be stated as follows:

Null Hypothesis: $H_0 : \mu_1 - \mu_2 = 0$.

Nondirectional Alternative Hypothesis: $H_1 : \mu_1 - \mu_2 \neq 0$.

A common application of nondirectional hypothesis testing involves conducting a t test and comparing the means of two groups. After calculating the t statistic, one can determine the critical value of t that designates the null hypothesis rejection region for a nondirectional or two-tailed test of significance. This critical value will depend on the degrees of freedom in the sample and the desired probability level, which is usually .05. The rejection region will be represented on both sides of the probability curve because a nondirectional hypothesis is sensitive to a larger or smaller effect.

Figure 1 shows a distribution in which at the 95% confidence level, the solid regions at the top and

bottom of the distribution represent 2.5% accumulated probability in each tail. If the calculated value for t exceeds the critical value at either tail of the distribution, then the null hypothesis can be rejected.

In contrast, the rejection region of a directional alternative hypothesis, or one-tailed test, would be represented on only one side of the distribution, because the hypothesis would choose a smaller or larger effect, but not both. In this instance, the critical value for t will be smaller because all 5% probability will be represented on one tail.

Much debate has occurred over the appropriate use of nondirectional and directional hypothesis in significance testing. Because the critical rejection values for a nondirectional test are higher than a directional test, it is a more conservative approach and the most commonly used. However, when prior research supports the use of a directional hypothesis test, a significant effect is easier to find and, thus, represents more statistical power. The researcher should state clearly the chosen alternative hypothesis and the rationale for this decision.

NONEXPERIMENTAL DESIGNS

Nonexperimental designs include research designs in which an experimenter either simply describes a group or examines relationships between preexisting groups. The members of the groups are not randomly assigned and an independent variable is not manipulated by the experimenter, thus no conclusions about causal relationships between variables in the study can be drawn. Generally, very little attempt is made to control for threats to internal validity in nonexperimental designs. Nonexperimental designs are used simply to answer questions about groups or about whether group

differences exist. The conclusions drawn from nonexperimental research are primarily descriptive in nature. Any attempts to draw conclusions about causal relationships based on nonexperimental research are done so post hoc. This entry begins by clarifying differences between the three primary types of research design and then provides an overview of various types of nonexperimental designs. Next, threats to internal validity are discussed. The entry concludes with some benefits of using nonexperimental design over other types of research design.

Differences Between Experimental, Quasi-Experimental, and Nonexperimental Designs

The crucial differences between the three main categories of research design lie in the assignment of participants to groups and in the manipulation of an independent variable. In experimental designs, members are randomly assigned to groups and the experimenter manipulates the values of the independent variable so that causal relationships may be established or denied. In quasi-experimental and nonexperimental designs, the groups already exist. The researcher cannot randomly assign the participants to groups because either the groups were already established before the researcher began their research or the groups are being established by someone other than the researcher for a purpose other than the experiment. In quasi-experimental designs, the experimenter can still manipulate the value of the independent variable, even though the groups to be compared are already established. In nonexperimental designs, the groups already exist and the researcher cannot or does not attempt to manipulate an independent variable. The researcher is simply comparing the existing groups based on a variable that the researcher did not manipulate. The researcher simply compares what is already established. Because the researcher cannot manipulate the independent variable, it is impossible to establish a causal relationship between the variables measured in a nonexperimental design.

A nonexperimental design may be used when an experimenter would like to know about the relationship between two variables, like the frequency of doctor visits for people who are obese compared to those who are of healthy weights or underweight. Clearly, from both an ethical and logistical standpoint, an experimenter could not simply randomly select three groups of people from a population and make one of the groups obese, one of the groups of healthy weights, and one of the groups underweight. The experimenter

could, however, find obese, healthy weight, and underweight people and record the number of doctor visits the members of each of these groups have in order to look at the relationship between the variables of interest. This nonexperimental design might yield important conclusions even though a causal relationship could not clearly be established between the variables.

Types of Nonexperimental Designs

Although researchers do not assign participants to groups in nonexperimental design, they can usually still determine what is measured and when it will be measured. So despite the lack of control in aspects of the experiment that are generally important to researchers, there are still ways in which researchers can control the data collection process in order to obtain interesting and useful data. Various authors classify nonexperimental designs in a variety of ways. Designs used in nonexperimental designs may include case studies, comparative designs, causal-comparative designs (which are also referred to as *differential* or *ex post facto* designs), correlational designs, and posttest-only nonequivalent groups designs. Both casual-comparative and posttest-only designs are sometimes referred to as *retrospective designs*. Survey research is often given as an example of nonexperimental research. While surveys are used frequently in nonexperimental research, they are also sometimes used in quasi-experimental and experimental research. Thus, it is not appropriate to consider surveys a nonexperimental design; rather, it should be considered a method most frequently used in nonexperimental research. The most important factor in a nonexperimental design is that there is no manipulation of any independent variables. The most important goal for the researcher is one of understanding what relationships between variables may exist, despite the fact that no causality can ever be determined using only nonexperimental designs.

Case Studies

There are numerous types of case studies that might be used in nonexperimental designs. The most common is a thorough examination of a particular case in which an extensive description of a case of interest is provided. The case may be chosen because of its uniqueness, its success, or its failure. For example, if one school in a low-performing district has particularly high rates of student success, researchers may choose to immerse themselves in the school and record anything that may be relevant to the success of the school. By then providing a thick description of the school, its environment, and its procedures, researchers might

learn a great deal about factors that may lead to success in a school.

One might also conduct a case-control study in which a case is compared to a control case. So the successful high school might be compared to another school in the district that has not had as much student success. Similarly, one might use a case series design in which a number of cases with a particular characteristic are studied. So a researcher could examine a number of successful students in a school with limited student success to provide a description of traits and habits of successful students in failing schools.

Comparative Designs

In these designs, two or more groups are compared on one or more measures. The experimenter may collect quantitative data and look for statistically significant differences between groups or collect qualitative data and compare the groups in a more descriptive manner. Of course, the researcher may also use mixed methods and do both of the aforementioned. Conclusions can be drawn about whether or not differences exist between groups, but the reasons for the differences cannot conclusively be drawn. The aforementioned study regarding obese, healthy weight, and underweight people's doctor visits is an example of a comparative design.

Causal-Comparative, Differential, or Ex Post Facto Research Designs

Nonexperimental research that is conducted when values of a dependent variable are compared based on a categorical independent variable is often referred to as a *causal-comparative* or a *differential design*. In these designs, the groups are determined by their values on some preexisting categorical variable, like gender. This design is also sometimes called *ex post facto* for that reason; the group membership is determined *after the fact*. After determining group membership, the groups are compared on the other measured dependent variable. The researcher then tests for statistically significant differences in the dependent variable between groups. Even though this design is referred to as causal-comparative, a causal relationship cannot be established using this design.

Correlational Designs

In correlational designs, the experimenter measures two or more nonmanipulated variables for each participant in order to ascertain whether or not linear relationships exist between the variables. The researcher

may use the correlations to conduct further regression analyses for predicting the values of one variable from another. No conclusions about causal relationships can be drawn from correlational designs. It is important to note, however, that correlational analyses may also be used to analyze data from experimental or quasi-experimental designs.

Posttest-Only Nonequivalent Control Group Design

In this type of between-subjects design, two nonequivalent groups of participants are compared. In nonexperimental research, the groups are almost always nonequivalent because the participants are not randomly assigned to groups. Because the researcher also does not control the intervention, this design is used when a researcher wants to study the impact of an intervention that already occurred. Given that pretest data cannot be collected, the researcher collects posttest data. However, in order to draw any conclusions about the posttest data, the researcher collects data from two groups, one that received the treatment or intervention, and one that did not. For example, if one is interested in knowing how participating in extracurricular sports during high school affects students' attitudes about the importance of physical fitness in adulthood, an experimenter might survey students during the final semester of their senior year. The researcher could survey a group that participated in sports and a group that did not. Clearly, the experimenter could not randomly assign students to participate or not participate. In this case, the researcher also could not compare the attitudes prior to participating with those following participation. With no pretest data, and with groups that are nonequivalent, the conclusions drawn from these studies may be lacking in internal validity.

Threats to Internal Validity

Internal validity is important in experimental research designs. It allows one to draw unambiguous conclusions about the relationship between two variables. When there is more than one possible explanation for the relationship between variables, the internal validity of the study is threatened. Because the experimenter has little control over potential confounding variables in nonexperimental research, the internal validity can be threatened in numerous ways.

Self-Selection

The most predominant threat with nonexperimental designs is due to the self-selection that often occurs by

the participants. Participants in nonexperimental designs often join the groups to be compared because of an interest in the group or because of life circumstances that place them in those groups. For example, if researchers wanted to compare the job satisfaction levels of people in three different kinds of careers such as business, academia, and food service, they would have to use three groups of people that either intentionally choose those careers or ended up in those careers due to life circumstances. Either way, the employees in those careers are likely to be in those different careers because they are different in other ways, such as educational background, skills, and interests. Thus, if researchers find differences in job satisfaction levels, they may be due to the fact that the participants are in different careers, or they may be due to the fact that people who are more satisfied with themselves overall choose careers in business, while those who do not consider their satisfaction in life choose careers in academia, and those who are between careers of their choosing opt for jobs in food service.

Another possibility is that people with more education are more satisfied with their jobs, and people in academia tend to be the most educated followed by those in business and then those in food service. Thus, if the researchers found that academicians are the most satisfied, it may be because of their jobs, or it may be because of their education. These proposed rationales are purely speculative; however, they demonstrate how internal validity may be threatened by self-selection. In both cases, a third variable exists that contributes to the differences between groups. Third variables can threaten internal validity in numerous ways with nonexperimental research.

Assignment Bias

Like self-selection, the assignment of participants to groups in a nonrandom method can create a threat to internal validity. While participants do not always self-select into groups used in nonexperimental designs, when they do not self-select, they are generally assigned to a group for a particular reason by someone other than the researcher. For example, if a researcher wanted to compare the vocabulary acquisition of students exposed to bilingual teachers in elementary schools, they might compare students taught by bilingual teachers with students taught by monolingual teachers in one school. Students may have been assigned to their classes for reasons related to their skill level in vocabulary-related tasks, like reading. Thus, any relationship the researcher finds may not be due to exposure to a bilingual teacher but due to a third variable, like reading level.

History and Maturation

In nonexperimental designs, an experimenter may simply look for changes across time in a group. Because the experimenter does not control the manipulation of the independent variable, or group assignment, both history and maturation can affect the measures collected from the participants. Some uncontrolled event (history) may occur that might confuse the conclusions drawn by the researcher. For example, in the aforementioned job satisfaction study, if the researcher was looking at changes in job satisfaction over time, and during the course of the study the stock market crashed, many of those with careers in business may have become more dissatisfied with their jobs due to that event. However, a stock market crash might not have affected academicians and food service workers to the same extent that it affected business workers. Thus, the conclusions that might be formed about the dissatisfaction of business employees would not have internal validity.

Similarly, in the vocabulary achievement example previously described, one would expect elementary students' vocabularies to improve simply due to maturation over the course of a school year. Thus, if the experimenter only looked for differences in vocabulary levels for students with bilingual teachers over the course of the school year, they might draw erroneous conclusions about the relationship between vocabulary performance and exposure to a bilingual teacher when in fact no relationship exists. This maturation of the students would be a threat to the internal validity of that study.

Response Bias

Response bias primarily affects survey research. When researchers administer surveys, either electronically or in person, some potential participants refuse to complete the surveys. There may be important differences between the respondents and nonrespondents that could be reflected in the data. For example, if researchers were collecting surveys following a workshop, those who choose to respond may be those who either felt the workshop was extremely valuable or had complaints to express. The nonrespondents might all be those who did not have extreme feelings about the workshop. Thus, the description about attendees' feelings toward the workshop that results from the survey responses is likely to be an inaccurate description of the general feelings of the audience.

Benefits of Using Nonexperimental Designs

Nonexperimental designs are often relied upon when a researcher has a question that requires a large group that cannot easily be assigned to groups. Nonexperimental designs may also be used when the population of interest is small and hard to access. Sometimes nonexperimental designs are used when a researcher simply wants to know something about a population but does not actually have a research hypothesis.

Although experimental designs are often utilized in both the hard and social sciences, there are numerous occasions in social sciences in which it is simply not possible to use an experimental design. This is especially true in fields like education or program evaluation, where the programs to be studied cannot simply be offered to a random set of participants from the population of interest. Rather, the educational program may already be in use in certain schools or classrooms. The researcher may have to determine how conclusions can be drawn based on the already established samples that are either participating or not participating in the intervention that is not controlled by the researcher. In such cases, it is preferable to use a nonexperimental design in order to acquire as much information about the program's effectiveness as possible rather than simply not attempting to study the effectiveness of the program.

Despite the fact that nonexperimental designs give the experimenter little control over the experimental process, the experimenter can improve the reliability of the findings by replicating the study. Additionally, one important feature of nonexperimental designs is the possibility of stronger ecological validity than one might obtain with a controlled, experimental design. Given that nonexperimental designs are often conducted with preexisting interventions with "real people" in the "real world," rather than participants in a laboratory, the findings are often more likely to be true to other real-world situations.

NONPARAMETRIC STATISTICS

Nonparametric statistics refer to methods of measurement that do not rely on assumptions that the data are drawn from a specific distribution. Nonparametric statistical methods have been widely used in various kinds of research designs to make statistical inferences. In practice, when the normality assumption on the measurements is not satisfied, parametric statistical methods might provide misleading results. In contrast, nonparametric methods make much less stringent distributional assumptions on the measurements. They are valid methods regardless of the underlying distributions of the observations. Because of this attractive advantage, ever since the first introduction of nonparametric tests in the last century, many different types of nonparametric tests have been developed to analyze various types of experimental designs. Such designs encompass one-sample design, two-sample design, randomized-block design, two-way factorial design, repeated measurements design, and highway layout. The observations in each experimental condition could be equal or unequal. The targeted inferences include the comparisons of treatment effects, the existence of interaction effects, ordered inferences of the effects, and multiple comparisons of the effects. All these methods share the same feature that instead of using the actual

observed measurements, they used the ranked values to form the statistics. By discarding the actual measurements, the methods gain the robustness to the underlying distributions and the potential contamination of outliers. This gain of robustness is only at the price of losing a relatively small amount of efficiency. In this entry, a brief review of the existing nonparametric methods is provided to facilitate the application of them in practical settings.

Tests for One or Multiple Populations

The Mann–Whitney–Wilcoxon (MWW) test is a nonparametric test to determine whether two samples of observations are drawn from the same distribution. The null hypothesis specifies that the two probability distributions are identical. It is one of the best-known nonparametric tests. It was first proposed by Frank Wilcoxon in 1945 for equal sample sizes, and it was later extended to arbitrary sample sizes by Henry B. Mann and Donald R. Whitney in 1947. To obtain the statistic, the observations are first ranked without regard to which sample they are in. Then for samples 1 and 2, the sum of ranks R_1 and R_2 , respectively, are computed. The statistic takes the form of

$$U = \min[R_1 - N_1(N_1 - 1)/2, R_2 - N_2(N_2 - 1)/2],$$

where N_1, N_2 denotes the samples sizes. For small samples, the distribution of the statistic is tabulated. However, for sample sizes greater than 20, the statistic can be normalized into

$$z = \frac{U - \frac{N_1 N_2}{2}}{\sqrt{\frac{N_1 N_2 (N_1 + N_2 + 1)}{12}}}.$$

The significance of the normalized statistic z can be assessed using the standard normal table. As a test to compare two populations, MWW is in spirit very similar to the parametric two-sample t test. In comparison, the parametric t test is more powerful if the data are drawn from normal distribution. In contrast, if the distributional assumption is violated in practice, then MWW is more powerful than its parametric counterpart. In terms of efficiency, under the normality assumption, the efficiency of MWW test is 95% of that of t test, which implies that to achieve the same power, the t test will need 5% less data points than the MWW test. Under other non-normal, especially heavy-tailed distributions, the efficiency of MWW could be much higher.

For the case of two related samples or repeated measurements on a single sample, the Wilcoxon

signed-rank test is a nonparametric alternative to the paired Student's t test. The null hypothesis to be tested is that the median of the paired differences is equal to zero. Let $(X_1, Y_1), \dots, (X_N, Y_N)$ denote the paired observations. The researcher computes the differences $d_i = X_i - Y_i, i = 1, \dots, N$, and omits those differences with zero values. Then, the remaining differences are ranked without regard to sign. The researcher then computes W_+ and W_- as the sums of the ranks corresponding to the positive and negative differences. If the alternative hypothesis specifies the median is greater, less than, or unequal, then the test statistic will be W_+, W_- , or $\min(W_+, W_-)$, respectively. For small samples with N less than 30, the table of critical values are tabulated, whereas N is large, normal approximation could be used to assess the significance. Note that the Wilcoxon signed-rank test can be used directly on one sample to test whether the population median is zero or not.

For comparisons of multiple populations, the nonparametric counterpart of the analysis of variance (ANOVA) test is the Kruskal–Wallis k -sample test proposed by William H. Kruskal and W. Allen Wallis in 1952. Given independent random samples of sizes $N_1, N_2, \dots, N_k$, drawn from k populations, the null hypothesis is that all the k populations are identical and have the same median; the alternative hypothesis is that at least one of the populations has a median different from the others. Let N denote the total number of measurements in the k samples, $N = \sum_{i=1}^k N_i$. Let R_i denote the sum of the ranks associated with the i th sample. It can be shown that the grand mean rank is $\frac{N+1}{2}$, whereas the sample mean rank for the i th sample is $\frac{R_i}{N_i}$.

The test statistic takes the form of

$$\frac{12}{N(N+1)} \sum_{i=1}^k N_i \left(\frac{R_i}{N_i} - \frac{N+1}{2} \right)^2.$$

The term of $\left(\frac{R_i}{N_i} - \frac{N+1}{2} \right)$ measures the deviation of the i th sample rank mean away from the grand rank mean. The term of $\frac{12}{N(N+1)}$ is the inverse of the variance of the total summation of ranks, and therefore it serves as a standardization factor. When N is fairly large, the asymptotic distribution of Kruskal–Wallis statistic can be approximated by the chi-squared distribution with $k - 1$ degrees of freedom.

Tests for Factorial Design

Test for Main Effects

In practice, data are often generated from experiments with several factors. To assess the individual factor effects in a nonparametric way, researchers could employ a rank transform method to test for the treatment effect of interest. Assume $X_{ijn} = \theta + \alpha_i + \beta_j + e_{ijn}$, while $i = 1, \dots, I$ indexes for the blocks, $j = 1, \dots, J$ indexes for the treatment levels, and $n = 1, \dots, N$ indexes for the replicates. The null hypothesis to be tested is $H_0: \beta_j = 0, j = 1, \dots, J$, versus the alternative hypothesis H_1 : at least one $\beta_j \neq 0$. The noises e_{ijn} are assumed to be independent and identically distributed with certain distribution F . The rank transform method proposed by W. J. Conover and Ronald L. Iman consists of replacing the observations by their ranks in the overall sample and then performing one of the standard ANOVA procedures on these ranks. Let R_{ijn} be the rank corresponding to the observation X_{ijn} , and $\bar{R}_{ij} = 1/N \sum_n R_{ijn}$, $\bar{R} = 1/(NI) \sum_i \sum_n R_{ijn}$. The Hora-Conover statistic proposed by Stephen C. Hora and Conover takes the form of

$$F = \frac{NI \sum_j (\bar{R}_{.j} - \bar{R}_{..})^2 / (J-1)}{\sum_i \sum_j \sum_k (R_{ijk} - \bar{R}_{ij})^2 / IJ(N-1)}.$$

When sample size is large, either the number of replicates per cell $N \rightarrow \infty$, or the number of blocks $I \rightarrow \infty$, the F statistic has a limiting χ^2_{J-1} distribution. The F statistic resembles the analysis of variance statistic in which the actual observation X_{ijk} s are replaced by R_{ijk} s. Such an analysis is easy to perform, as most software implement ANOVA procedures. This method has wide applicability in the analysis of experimental data because of its robustness and simplicity in use.

However, the Hora-Conover statistic F cannot handle unbalanced designs that often arise in practice. Consider the following unbalanced design:

$$X_{ijn} = \theta + \alpha_i + \beta_j + \epsilon_{ijn},$$

where $i = 1, \dots, I$ and $j = 1, \dots, J$ index levels for factors A and B, respectively, and $n = 1, \dots, n_{ij}$, $N = \sum_{ij} n_{ij}$. We wish to test the hypothesis: $H_0: \beta_j = 0 \forall j$ versus $H_1: \beta_j \neq 0$ for some j . To address the problem of unbalance in designs, let us examine the composition of a traditional rank. Define the function $u(x) = 1$ if $x \geq 0$; and $u(x) = 0$ if $x < 0$ and note that

$$R_{ijn} = \sum_{i'} \sum_{j'} \sum_{n'}^{n_{ij}} u(X_{ijn} - X_{i'j'n'}).$$

Thus, the overall rankings do not adjust for different sample sizes in unbalanced designs. To address this problem, we define the notion of a weighted rank.

Definition

Let $\Omega = \{X_{ijn}, i = 1, \dots, I, j = 1, \dots, J, n = 1, \dots, n_{ij}\}$ be a collection of random variables. The weighted rank of X_{ijn} within this set is

$$R_{ijn}^* = \frac{N}{IJ} \sum_{i'j'n'} \frac{1}{n_{i'j'}} \left[\sum_{n'} u(X_{ijn} - X_{i'j'n'}) \right],$$

$$\text{where } N = \sum_{ij} n_{ij}.$$

Define $S_N^* = [S_N^*(j), j = 1, \dots, J]$ to be a vector of weighted linear rank statistics with components $S_N^*(j) = \frac{1}{IJ} \sum_i \frac{1}{n_{ij}} \sum_{n=1}^{n_{ij}} R_{ijn}^*$. Let $\bar{S}_N^* = \frac{1}{J} \sum_j S_N^*(j)$. Denote the covariance matrix of S_N^* as $\Sigma = (\sigma_{b,b'})$, with $b, b' = 1, \dots, J$. To estimate σ we construct a variable C_{ijn}^b

$$C_{ijn}^b = -\frac{1}{IJ^2 \rho_{ij}} (R_{ijn}^* / N), j \neq b$$

$$\frac{J-1}{IJ^2 \rho_{ib}} (R_{ibn}^* / N), j = b. \quad (1)$$

Let $\hat{\sigma}_N(b, b') = \sum_i \sum_j \sum_{n'} (C_{ijn}^b - \bar{C}_{ij}^b)^2$, and $\hat{\sigma}_N(b, b') = \sum_i \sum_j \sum_{n'} (C_{ijn}^b - \bar{C}_{ij}^b)(C_{ijn}^{b'} - \bar{C}_{ij}^{b'})$. Let $\hat{\Sigma}_N$ be the $J \times J$ matrix of $[\hat{\sigma}_N(b, b')], b, b' = 1, \dots, J$. The fact that R_{ijn}^* / N converges to $H(X_{ijn})$ almost surely leads to the fact that under $H_0, \forall j, \frac{1}{N} (\sum_N - \hat{\Sigma}_N) \rightarrow 0$ a.s. elementwise.

Construct a contrast matrix $A = I_J - \frac{1}{J} J_J$. The generalized Hora-Conover statistic proposed by Xin Gao and Mayer Alvo for the main effects in unbalanced designs takes the form

$$T_M = (AS_N^*)' (A \hat{\Sigma}_N A')^{-1} (AS_N^*),$$

in which the general inverse of the covariance matrix is employed. The statistic T_M is invariant with respect to choices of the general inverses. When the design is balanced, the test statistic is equivalent to the Hora-Conover statistic. This statistic T_M converges to a central χ^2_{J-1} as $N \rightarrow \infty$.

Test for Nested Effects

Often, practitioners might speculate that the different factors might not act separately on the response and interactions might exist between the factors. In

light of such a consideration, one could study an unbalanced two-way layout with an interaction effect. Let $X_{ijn}(i = 1, \dots, I; j = 1, \dots, J; n = 1, \dots, n_{ij})$ be a set of $N = \sum_i \sum_j n_{ij}$ independent random variables with the model

$$X_{ijn} = \theta + \alpha_i + \beta_j + \gamma_{ij} + \varepsilon_{ijn}, \quad (2)$$

where i and j index levels for factors A and B, respectively. Assume $\sum_i \alpha_i = \sum_j \beta_j = \sum_{ij} \gamma_{ij} = \sum_{ij} \gamma_{ij} = 0$ and ε_{ijn} are independent and identically distributed (i.i.d.) random variables with absolute continuous cumulative distribution function (cdf) F . Let $\delta_{ij} = \beta_j + \gamma_{ij}$. To test for nested effect, we consider testing $H_0 : \delta_{ij} = 0, \forall i$ and j versus $H_1 : \delta_{ij} \neq 0$, for some i and j . The nested effect can be viewed as the combined overall effect of the treatment either through its own main effect or through its interaction with the block factor.

The same technique of using weighted rank can be applied in testing for nested effects. Define $S_N^*(i, j) = 1/n_{ij} \sum_n R_{ijn}^*$ and let S_N^* be the IJ vector of $[S_N^*(i, j), 1 \leq i \leq I, 1 \leq j \leq J]$. Construct a contrast matrix $B = I_I \otimes (I_J - \frac{1}{J} J_J)$, such that the ij element of BS_N^* is $S_N^*(i, j) - \frac{1}{J} \sum_{b=1}^J S_N^*(i, b)$. Let Γ denote the covariance matrix of S_N^* . To facilitate the estimation of Γ , we define the following variables:

$$C^{(i,j)}(X_{abn}) = \begin{cases} \frac{N}{IJn_{ab}n_{ij}} \sum_{k=1}^{n_{ij}} u(X_{abn} X_{ijk}) \text{ for } (a, b) \neq (i, j), \\ l \frac{N}{IJn_{ij}} \sum_{(i', j') \neq (i, j)} \frac{1}{n_{i', j'}} \sum_{n'=1}^{n_{i', j'}} u(X_{ijn} - X_{i', j', n'}) \text{ for } (a, b) = (i, j) \end{cases} \quad (3)$$

Let $\hat{\Gamma}_N$ matrix with elements

$$\hat{\gamma}_N[(i, j), (i', j')] = \sum_{a, b, n} (C^{(i,j)}(X_{abn}) - \bar{C}^{(i,j)}[X_{ab.}]) [C^{(i', j')}(X_{abn}) - \bar{C}^{(i', j')}(X_{ab.})],$$

where $\bar{C}^{(i,j)}(X_{ab.}) = \frac{1}{n_a b} \sum_n C^{(i,j)}(X_{abn})$. It can be proved that $1/\sqrt{N}(\hat{\gamma}_N - \gamma_N) \rightarrow 0$ almost surely elementwise. The proposed test statistic T_N for nested effects takes the form

$$(BS_N^*)' (B\hat{\Gamma}_N B')^{-1} (BS_N^*).$$

Under $H_0 : \delta_{ij} = 0, \forall i, j$, the proposed statistic T_N converges to a central $\chi_{I(J-1)}^2$ as $N \rightarrow \infty$.

Tests for Pure Nonparametric Models

The previous discussion has been focused on the linear model with the error distribution unspecified. To reduce the model assumption, Michael G. Akritas, Steven F. Arnold, and Edgar Brunner have proposed a nonparametric framework in which the structures of the designs are no longer restricted to linear location models. The nonparametric hypotheses are formulated in terms of linear contrasts of normalized distribution functions. One advantage of the nonparametric hypotheses is that the parametric hypotheses in linear models are implied by the nonparametric hypotheses. Furthermore, the nonparametric hypotheses are not restricted to continuous distribution functions and therefore any models with discrete observations might also be included in this setup.

Under this nonparametric setup, the response variables in a two-way unbalanced layout with I treatments and J blocks can be described by the following model:

$$X_{ijn} : F_{ij}(x), i = 1, \dots, I, j = 1, \dots, J, \\ n = 1, \dots, n_{ij} \quad (2)$$

where $F_{ij}(x) = \frac{1}{2} [F_{ij}^+(x) + F_{ij}^-(x)]$ denotes the normalized-version of the distribution function, $F_{ij}^+(x) = P(X_{ijn} \leq x)$ denotes the right continuous version, and $F_{ij}^-(x) = P(X_{ijn} \leq x)$ denotes the left continuous version. The normalized version of the distribution function accommodates both ties and ordinal data. Compared with the classic ANOVA models, this nonparametric framework is different in two aspects: First, the normality assumption is relaxed; second, it not only includes the commonly used location models but also encompasses other arbitrary models with different cells having different distributions. Under this nonparametric setting, the hypotheses can be formulated in terms of linear contrasts of the distribution functions. According to Akritas and Arnold's method, F_{ij} can be decomposed as follows:

$$F_{ij}(y) = M(y) + A_i(y) + B_j(y) + C_{ij}(y),$$

where $\sum_i A_i = \sum_j B_j = 0$, and $\sum_i C_{ij} = 0$, for all j , and $\sum_j C_{ij} = 0$, for all i . It follows that $M = \bar{F}_{..}$, $A_i = \bar{F}_{i.} - M$, $B_j = \bar{F}_{.j} - M$, and $C_{ij} = F_{ij} - \bar{F}_{i.} - \bar{F}_{.j} + M$, where the subscript “.” denotes summing over all values of the index. Denote the treatment factor as factor A and the block factor as factor B. The overall nonparametric hypotheses of no treatment main effects and no treatment simple factor effects are specified as follows:

$$H_0(A) : \bar{F}_{i\cdot} - \bar{F}_{\cdot\cdot} = 0, \forall i = 1, \dots, I;$$

$$H_0(A|B) : F_{ij} - \bar{F}_{i\cdot} = 0, \forall i = 1, \dots, I, \forall j = 1, \dots, J.$$

The hypothesis $H_0(A|B)$ implies that the treatment has no effect on the response either through the main effects or through the interaction effects.

This framework especially accommodates the analysis of interaction effects in a unified manner. In literature, testing interactions using ranking methods have been a controversial issue for a long time. The problem pertaining to the analysis of interaction effects is because the interaction effects based on cell means can be artificially removed or introduced after certain nonlinear transformations. As rank statistics are invariant to nonlinear monotone transformations, they cannot be used to test for hypotheses that are not invariant to monotone transformations. To address this problem, Akritas and Arnold proposed to define nonparametric interaction effects in terms of linear contrasts of the distribution functions. Such nonparametric formulation of interaction effects is invariant to monotone transformations. The nonparametric hypothesis of no interaction assumes the additivity of the distribution functions and is defined as follows:

$$H_0(AB) : F_{ij} - \bar{F}_{i\cdot} - \bar{F}_{\cdot j} + \bar{F}_{\cdot\cdot} = 0, \forall i = 1, \dots, I, \forall j = 1, \dots, J.$$

This implies the distribution in the (i, j) th cell, F_{ij} , is a mixture of two distributions, one depending on i and the other depending on j , and the mixture parameter is the same for all (i, j) . It is noted that all the nonparametric hypotheses bear analogous representation to their parametric counterparts except the parametric means are replaced by the distribution functions. Furthermore, all the nonparametric hypotheses are stronger than the parametric counterparts.

As no parameters are involved in the general model in Equation 4, the distribution functions $F_{ij}(x)$ can be used to quantify the treatment main effects, the treatment simple factor effects, and the interaction effects. To achieve this goal, Brunner and M. L. Puri considered the unweighted relative effects, which take the form

$$\pi_{ij} = \int H^* dF_{ij}, i = 1, \dots, I, j = 1, \dots, J, \quad (5)$$

where $H^*(x) = \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J F_{ij}(x)$ is the average distribution function in the experiment. Denote $\mathbf{F} = (F_{11}, \dots, F_{IJ})'$ as the vector of the distribution functions. In general, the measure π_{ij} should be interpreted as the probability that the random variable generated from F_{ij} will tend to be larger than a random variable

generated from the average distribution function H^* . In the special case of shift models or by assuming non-crossing cumulative distribution functions, the relative effects π_{ij} define a stochastic order by $F_{ij} <, =, > H^*$, according as $\pi_{ij} <, =, \text{ or } > \frac{1}{2}$. In practice, the definition

of a relative effect is particularly convenient for ordinal data. As the differences of means can only be defined with metric scales, the parametric approach of comparing two treatments based on means is not applicable on ordinal scales. However, the points of an ordinal scale can be ordered by size, which can be used to form the estimate of the nonparametric relative effects.

Let $\boldsymbol{\pi} = (\pi_{11}, \dots, \pi_{IJ})' = \int H^* d\mathbf{F}$ denote the vector of the relative effects. The relative effects π_{ij} can be estimated by replacing the distribution functions $F_{ij}(x)$ by their empirical counterparts

$$\hat{F}_{ij}(x) = \frac{1}{2} [\hat{F}_{ij+}(x) + \hat{F}_{ij-}(x)] = \frac{1}{n_{ij}} \sum_{k=1}^{n_{ij}} (x - X_{ijk}),$$

where $c(u) = \frac{1}{2} [c^+(u) + c^-(u)]$ denotes the indicator function with $c^+(u) = 0$ or 1 depending on whether $u < 0$ or ≥ 0 , and $c^-(u) = 0$ or 1 depending on whether $u \leq 0$ or > 0 . The vector of the empirical distribution functions is denoted by $\hat{\mathbf{F}} = (\hat{F}_{11}, \dots, \hat{F}_{IJ})'$. The average empirical distribution function is denoted as $\hat{H}^*(x) = \frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J \hat{F}_{ij}(x)$. Then, the vector of the unweighted relative effects is estimated unbiasedly by $\hat{\boldsymbol{\pi}} = \int H^* d\hat{\mathbf{F}} = \frac{1}{N} \bar{\mathbf{R}}^*$, where $N = \sum_i \sum_j n_{ij}$, $\bar{\mathbf{R}}^* = (\bar{R}_{11}^*, \dots, \bar{R}_{IJ}^*)'$, $\bar{R}_{ij}^* = \frac{1}{n_{ij}} \sum_{k=1}^{n_{ij}} R_{ijk}^*$, and $R_{ijk}^* = \frac{N}{IJ} \sum_{i'=1}^I \frac{1}{n^{i'j'}} \sum_{k'=1}^{n_{i'j'}} (x - X_{i'j'k'})$. The latter is the weighted rank of the observation X_{ijk} among all the observations proposed by Sebastian Domhof, Gao, and Alvo.

Focusing on the problem of hypothesis testing in unbalanced two-way layouts, with $H_0 : \mathbf{CF} = \mathbf{0}$, versus $H_0 : \mathbf{CF} \neq \mathbf{0}$, and $\mathbf{C}$ being a IJ by IJ contrast matrix. It can be shown that the testing main effects, nested effects, or interaction effects can all be expressed in such a general form. Assume that as $\min\{n_{ij}\} \rightarrow \infty$, $\lim_{N \rightarrow \infty} n_{ij}/N = \lambda_{ij}$, and $\sigma_{ij}^2 = \text{var}[H^*(X_{ijk})] > 0$, for all i and j . Then, an application of the Lindeberg-Feller theorem yields $\sqrt{N}(\mathbf{C}\hat{\boldsymbol{\pi}}) \xrightarrow{d} N(0, \mathbf{CVC}')$, with $\mathbf{V} = \text{diag}(\frac{1}{\lambda_{11}} \sigma_{11}^2, \dots, \frac{1}{\lambda_{IJ}} \sigma_{IJ}^2)$. The asymptotic variance σ_{ij}^2 , $i = 1, \dots, I$, and $j = 1, \dots, J$, can be estimated from the pseudo ranks as $\hat{\sigma}_{ij}^2 = \frac{1}{N^2(n_{ij}-1)} \sum_{k=1}^{n_{ij}} (R_{ijk}^* - \bar{R}_{ij}^*)^2$,

and the estimated covariance matrix takes the form of $\hat{V} = \text{diag}(\frac{1}{\lambda_{11}}\hat{\sigma}_{11}^2, \dots, \frac{1}{\lambda_{JJ}}\hat{\sigma}_{JJ}^2)$. The fact that R_{ijk}^*/N converges to $H^*(X_{ijk})$ almost surely leads to the result that $V - \hat{V} \xrightarrow{a.s.} 0$ elementwise. Therefore, we consider the test statistic $T = \sqrt{N}\hat{\pi}C'(\hat{C}\hat{V}C')^{-}C\hat{\pi}$, where $(\hat{C}\hat{V}C')^{-}$ denotes the general inverse of $(\hat{C}\hat{V}C')$. According to Slutsky's theorem, because $\hat{V}$ is consistent, we have $T \xrightarrow{d} \chi_f^2$, where the degrees of freedom $f = \text{rank}(C)$.

Conclusions

Nonparametric methods have wide applicabilities in the analysis of experimental data because of their robustness to the underlying distributions and insensitivity to potential outliers. In this entry, various methods to test for different effects in a factorial design have been reviewed. It is worthy to emphasize that in the situation where the normality assumption is violated, nonparametric methods are powerful alternative approaches to make sounded statistical inference for experimental data.

NONPARAMETRIC STATISTICS FOR THE BEHAVIORAL SCIENCES

Sidney Siegel (January 4, 1916–November 29, 1961) was a psychologist trained at Stanford University. He spent nearly his entire career as a professor at Pennsylvania State University. He is known for his contribution to nonparametric statistics, including the development with John Tukey of the Siegel–Tukey test—a test for differences in scale between groups. Arguably, he is most well known for his book, *Nonparametric Statistics for the Behavioral Sciences*, the first edition of which was published by McGraw-Hill in 1956. After Siegel's death, a second edition was published (1988) adding N. John Castellan Jr. as coauthor. *Nonparametric Statistics for the Behavioral Sciences* is the first text to provide a practitioner's introduction to nonparametric statistics. By its copious use of examples and its straightforward “how to” approach to the most frequently used nonparametric tests, this text was the first accessible introduction to nonparametric statistics for the nonmathematician. In that sense, it represents an important step forward in the analysis and presentation of non-normal data, particularly in the field of psychology.

The organization of the book is designed to assist the researcher in choosing the correct nonparametric test. After the introduction, the second chapter introduces the basic principles of hypothesis testing, including the definitions of: the null and alternative hypothesis, the size of the test, Type I and Type II errors, power, sampling distributions, and the decision rule. Chapter 3 describes the factors that influence the choice of correct test. After explaining some common parametric assumptions and the circumstances under which

nonparametric tests should be used, the text gives a basic outline of how the proper statistical test should be chosen. Tests are distinguished from one another in two important ways: First, tests are distinguished by their capability of analyzing data of varying levels of measurement. For example, the χ^2 goodness-of-fit test can be applied to nominal data, whereas the Kolmogorov–Smirnov requires at least the ordinal level of measurement. Second, tests are distinguished in terms of the type of samples to be analyzed. For example, two-sample paired tests are distinguished from tests applicable to k independent samples, which are distinguished tests of correlation, and so on. Tests included in the text include the following: the binomial test, the sign test, the signed-rank test, tests for data displayed in two-way tables, the Mann–Whitney U test, the Kruskal–Wallis test, and others. Also included are extensive tables of critical values for the various tests discussed in the text.

Because nonparametric tests make fewer assumptions than parametric tests, they are generally less powerful than the parametric alternatives. The text compares the various tests presented with their parametric analogues in terms of power efficiency. Power efficiency is defined to be the percent decrease in sample size required for the parametric test to achieve the same power as that of the nonparametric test when the test is performed on data that do, in fact, satisfy the assumptions of the parametric test.

This work is important because it seeks to present nonparametric statistics in a way that is “completely intelligible to the reader whose mathematical training is limited to elementary algebra” (Siegel, 1956, p. 4). It is replete with examples to demonstrate the application of these tests in contexts that are familiar to psychologists and other social scientists. The text is organized so that the user, knowing the specific level of measurement and type(s) of samples being analyzed, can immediately identify several nonparametric tests that might be applied to his or her data.

Included in each test is a description of its function (under what circumstances this particular test should be used), rationale, and method (a heuristic description of why the test works and how the test statistic is calculated) including any modifications that exist and the procedure for dealing with ties, both large and small sample examples, a numbered list of steps for performing the test, and other references for a more in-depth description of the test.

NONPROBABILITY SAMPLING

The two kinds of sampling techniques are probability and nonprobability sampling. Probability sampling is based on the notion that the people or events chosen are selected because they are representative of the entire population. Nonprobability refers to procedures in which researchers select their sample elements not based on a predetermined probability. This entry examines the application, limitations, and utility of nonprobability sampling procedures. Conceptual and empirical strategies to use nonprobability sampling techniques more effectively are also discussed.

Sampling Procedures

Probability Sampling

There are many different types of probability sampling procedures. More common ones include simple, systematic, stratified, multistage, and cluster sampling. Probability sampling allows one to have confidence that the results are accurate and unbiased, and it allows one to estimate how precise the data are likely to be. The data from a properly drawn sample are superior to data drawn from individuals who just show up at a meeting or perhaps speak the loudest and convey their personal thoughts and sentiments. The critical issues in sampling include whether to use a probability sample, the sampling frame (the set of people that have a chance of being selected and how well it corresponds to the population studied), the size of the sample, the sample design (particularly the strategy used to sample people, schools, households, etc.), and the response rate. The details of the sample design, including size and selection procedures, influence the precision of sample estimates regarding how likely the sample is to approximate population characteristics. The use of standardized measurement tools and procedures also helps to assure comparable responses.

Nonprobability Sampling

Nonprobability sampling is conducted without the knowledge about whether those chosen in the sample are representative of the entire population. In some instances, the researcher does not have sufficient information about the population to undertake probability

sampling. The researcher might not even know who or how many people or events make up the population. In other instances, nonprobability sampling is based on a specific research purpose, the availability of subjects, or a variety of other nonstatistical criteria. Applied social and behavioral researchers often face challenges and dilemmas in using a random sample, because such samples in a real-world research are “hard to reach” or not readily available. Even if researchers have contact with hard-to-reach samples, they might be unable to obtain a complete sampling frame because of peculiarities of the study phenomenon. This is especially true when studying vulnerable or stigmatized populations, such as children exposed to domestic violence, emancipated foster care youth, or runaway teenagers. Consider for instance the challenges of surveying adults with the diagnosis of paranoid personality disorder. This is not a subgroup that is likely to agree to sign a researcher’s informed consent form, let alone complete a lengthy battery of psychological instruments asking a series of personal questions.

Applied researchers often encounter other practical dilemmas when choosing a sampling method. For instance, there might be limited research resources. Because of limitations in funding, time, and other resources necessary for conducting large-scale research, researchers often find it difficult to use large samples. Researchers employed by a single site or agency might be unable to access subjects served by other agencies located in other sites. It is not a coincidence that recruiting study subjects from a single site or agency is one of the most popular methods among studies using nonprobability procedures. The barriers preventing a large-scale multisite collaboration among researchers can be formidable and difficult to overcome.

Statistical Theories About Sampling Procedures

Because a significant number of studies employ nonprobability samples and at the same time apply inferential statistics, it is important to understand the consequences. In scientific research, there are many reasons to observe elements of a sample rather than a population. Advantages of using sample data include reduced cost, greater speed, greater scope, and greater accuracy. However, there is no reason to use a biased sample that does not represent a target population. Scientists have given this topic a rigorous treatment and developed several statistical theories about sampling procedures. Central limit theorem, which is usually given in introductory statistics courses, forms the foundation of probability-sampling techniques. At the core of this theorem are the proven relationships

between the mean of a sampling distribution and the mean of a population, between the standard deviation of a sampling distribution (known as standard error) and the standard deviation of a population, and between the normal sampling distribution and the possible non-normal population distribution.

Statisticians have developed various formulas for estimating how closely the sample statistics are clustered around the population true values under various types of sampling designs, including simple random sampling, systematic sampling, stratified sampling, clustered sampling, and multistage clustered and stratified sampling. These formulas become the yardstick for determining adequate sample size. Calculating the adequacy of probabilistic sample size is generally straightforward and can be estimated mathematically based on preselected parameters and objectives (i.e., α statistical power with y confidence intervals). In practice, however, sampling error—the key component required by the formulas for figuring out a needed sample size—is often unknown to researchers. In such instances, which often involve quasi-experimental designs, Jacob Cohen’s framework of statistical power analysis is employed instead. This framework concerns the balance among four elements of a study: sample size, effect size or difference between comparison groups, probability of making a Type I error, and probability of denying a false hypothesis or power. Studies using small nonprobability samples, for example, are likely to have an inadequate power (significantly below .85 convention indicating an adequate power). As a consequence, studies employing sophisticated analytical models might not meet the required statistical criteria. The ordinary least-square regression model, for example, makes five statistical assumptions about data, and most of the assumptions require a randomized process for data gathering. Violating statistical assumptions in a regression analysis refers to the presence of one or more detrimental problems such as heteroscedasticity, autocorrelation, non-normality, multicollinearity, and others. Multicollinearity problems are particularly likely to occur in nonprobability studies in which data were gathered through a sampling procedure with hidden selection bias and/or with small sample sizes. Violating statistical assumptions might increase the risk of producing biased and inefficient estimates of regression coefficients and exaggerated R^2 .

Guidelines and Recommendations

This brief review demonstrates the importance of using probability sampling; however, probability sampling cannot be used in all instances. Therefore, the following questions must be addressed: Given the sampling

dilemmas, what should researchers do? How can researchers using nonprobability sampling exercise caution in reporting findings or undertake remedial measures? Does nonprobability sampling necessarily produce adverse consequences? It is difficult to offer precise remedial measures to correct the most commonly encountered problems associated with the use of nonprobability samples because such measures vary by the nature of research questions and type of data researchers employ in their studies. Instead of offering specific measures, the following strategies are offered to address the conceptual and empirical dilemmas in using nonprobability samples.

George Judge et al. caution researchers to be aware of assumptions embedded in the statistical models they employ, to be sensitive to departures of data from the assumptions, and to be willing to take remedial measures. John Neter et al. recommend that researchers always perform diagnostic tests to investigate departures of data from the statistical assumptions and take corrective measures if detrimental problems are present. In theory, all research should use probabilistic sampling methodology, but in practice this is difficult especially for hard-to-reach, hidden, or stigmatized populations. Much of social science research can hardly be performed in a laboratory. It is important to stress that the results of the study are meaningful if they are interpreted appropriately and used in conjunction with statistical theories. Theory, design, analysis, and interpretation are all connected closely.

Researchers are also advised to study compelling populations and compelling questions. This most often involves purposive samples in which the research population has some special significance. Most commonly used samples, particularly in applied research, are purposive. Purposive sampling is more applicable in exploratory studies and studies contributing new knowledge. Therefore, it is imperative for researchers to conduct a thorough literature review to understand the “edge of the field” and whether the study population or question is a new or significant contribution. How does this study contribute uniquely to the existing research knowledge? Purposive samples are selected based on a predetermined criteria related to the research. Research that is field oriented and not concerned with statistical generalizability often uses nonprobabilistic samples. This is especially true in qualitative research studies. Adequate sample size typically relies on the notion of “saturation,” or the point in which no new information or themes are obtained from the data. In qualitative research practice, this can be a challenging determination.

Researchers should also address subject recruitment issues to reduce selection bias. If possible, researchers

should use consecutive admissions including all cases during a representative time frame. They should describe the population in greater detail to allow for cross-study comparisons. Other researchers will benefit from additional data and descriptors that provide a more comprehensive picture of the characteristics of the study population. It is critical in reporting results (for both probability and nonprobability sampling) to tell the reader who was or was not given a chance to be selected. Then, to the extent that is known, researchers should tell the reader how those omitted from the study are the same or different from those included. Conducting diagnostics comparing omitted or lost cases with the known study subjects can help in this regard. Ultimately, it is important for researchers to indicate clearly and discuss the limits of generalizability and external validity.

In addition, researchers are advised to make efforts to assure that a study sample provides adequate statistical power for hypothesis testing. It has been shown that other things being equal, a large sample always produces more efficient and unbiased estimates about population-true parameters than a small sample. When the use of a nonprobability sample is inevitable, researchers should carefully weigh the pros and cons that are associated with different study designs and choose a sample size that is as large as possible.

Another strategy is for researchers to engage in multi-agency research collaborations that generate samples across agencies and/or across sites. In one study, because of limited resources, Brent Benda and Robert Flynn Corwyn found it unfeasible to draw a nationally representative sample to test the mediating versus moderating effects of religion on crime in their study. To deal with the challenge, they used a comparison between two carefully chosen sites: random samples selected from two public high schools involving 360 adolescents in the inner city of a large east coast metropolitan area and simple random samples involving 477 adolescents from three rural public high schools in an impoverished southern state. The resultant data undoubtedly had greater external validity than studies based on either site alone.

If possible, researchers should use national samples to run secondary data analyses. These databases were created by probability sampling and are deemed to have a high degree of representativeness and other desirable properties. The drawback is that these databases are likely to be useful for only a minority of research questions.

Finally, does nonprobability sampling necessarily produce adverse consequences? Shenyang Guo and David L. Hussey have shown that a homogeneous sample produced by nonprobability sampling is better

than a less homogeneous sample produced by probability sampling in prediction. Remember, regression is a leading method used by applied researchers employing inferential statistics. Regression-type models also include simple linear regression, multiple regression, logistic regression, structural equation modeling, analysis of variance (ANOVA), multivariate analysis of variance (MANOVA), and analysis of covariance (ANCOVA). In a regression analysis, a residual is defined as the difference between the observed value and model-predicted value of the dependent variable. Researchers are concerned about this measure because it is the model with the smallest sample residual that gives the most accurate predictions about sample subjects. Statistics such as Theil's U can gauge the scope of sample residuals, which is a modified version of root-mean-square error measuring the magnitude of the overall sample residual. The statistic ranges from zero to one, with a value closer to zero indicating a smaller overall residual. In this regard, nonprobability samples can be more homogeneous than a random sample. Using regression coefficients (including an intercept) to represent study subjects, it is much easier to obtain an accurate estimate for a homogeneous sample than for a heterogeneous sample. This consequence, therefore, is that small homogeneous samples generated by a nonprobability sampling procedure might produce more accurate predictions about sample subjects. Therefore, if the task is not to infer statistics from sample to population, using a nonprobability sample is a better strategy than using a probability sample.

With the explosive growth of the World Wide Web and other new electronic technologies such as search monkeys, nonprobability sampling remains an easy way to obtain feedback and collect information. It is convenient, verifiable, and low cost, particularly when compared with face-to-face paper-and-pencil questionnaires. Along with the benefits of new technologies, however, the previous cautions apply and might be even more important given the ease with which larger samples might be obtained.

NONSIGNIFICANCE

This entry defines nonsignificance within the context of null hypothesis significance testing (NHST), the dominant scientific statistical method for making inferences about populations based on sample data. Emphasis is placed on the three routes to nonsignificance: a real lack of effect in the population; failure to detect a real effect because of an insufficiently large sample; or failure to detect a real effect because of a methodological flaw. Of greatest importance is the recognition that nonsignificance is not affirmative evidence of the absence of an effect in the population.

Nonsignificance is the determination in NHST that no statistically significant effect (e.g., correlation, difference between means, and dependence of proportions) can be inferred for a population. NHST typically involves statistical testing (e.g., *t* test) performed on a sample to infer whether two or more variables are related in a population. Studies often have a high probability of failing to reject a false null hypothesis (i.e., commit a Type II, or false negative, error), thereby returning a nonsignificant result even when an effect is present in the population.

In its most common form, a null hypothesis posits that the means on some measurable variable for two groups are equal to each other. A statistically significant difference would indicate that the probability that a true null hypothesis is erroneously rejected (Type I, or false positive, error) is below some desired threshold (α), which is typically .05. As a result, statistical significance refers to a conclusion that there likely is a difference in the means of the two population groups. In contrast, nonsignificance refers to the finding that the two means do not significantly differ from each other (a failure to reject the null hypothesis). Importantly, nonsignificance does not indicate that the null hypothesis is true, it only indicates that one cannot rule out chance and random variation to explain observed differences. In this sense, NHST is analogous to an American criminal trial, in which there is a presumption of innocence (equality), the burden of proof is on demonstrating guilt (difference), and a failure to convict (reject the null hypothesis) results only in a verdict

of “not guilty” (not significant), which does not confer innocence (equality).

Nonsignificant findings might reflect accurately the absence of an effect or might be caused by a research design flaw leading to low statistical power and a Type II error. Statistical power is defined as the probability of detecting an existing effect (rejecting a false null hypothesis) and might be calculated *ex ante* given the population effect size (or an estimate thereof), the desired significance level (e.g., .05), and the sample size.

Type II errors resulting from insufficient statistical power can result from several factors. First, small samples yield lower power because they are simply less likely than large samples to be representative of the population, and they lead to larger estimates of the standard error. The standard error is estimated as the sample standard deviation divided by the square root of the sample size. Therefore, the smaller the sample, the bigger the estimate of the standard error will be. Because the standard error is the denominator in significance test equations, the bigger it is, the less likely the test statistic will be large enough to reject the null hypothesis. Small samples also contribute to nonsignificance because sample size (specifically, the degrees of freedom that are derived from it) is an explicit factor in calculations of significance levels (*p* values). Low power can also result from imprecise measurement, which might result in excessive variance. This too will cause the denominator in the test statistic calculation to be large, thereby underestimating the magnitude of the effect.

Type II error can also result from flawed methodology, wherein variables are operationalized inappropriately. If variables are not manipulated or measured well, the real relationship between the intended variables will be more difficult to discern from the data. This issue is often referred to as *construct validity*. A nonrepresentative sample, even if it is large, or a misspecified model might also prevent the detection of an existing effect.

To reduce the likelihood of nonsignificance resulting from Type II errors, an *a priori* power analysis can determine the necessary sample size to provide the desired likelihood of rejecting the null hypothesis if it is false. The suggested convention for statistical power is .8. Such a level would allow a researcher to say with 80% confidence that no Type II error had been committed and, in the event of nonsignificant findings, that no effect exists.

Some have critiqued the practice of reporting significance tests alone, given that with a .05 criterion, determining that a result of .049 is statistically significant, whereas one of .051 is not artificially dichotomizes the determination of significance. An overreliance on

statistical significance also results in a bias among published research for studies with significant findings, contributing to a documented upward bias in effect sizes in published studies. Directional hypotheses might also be an issue. For accurate determination of significance, directionality should be specified in the design phase, as directional hypotheses (e.g., predicting that one particular mean will be higher than the other) have twice the statistical power of nondirectional hypotheses, provided the results are in the hypothesized direction.

Many of these problems can be avoided with a careful research design that incorporates a sufficiently large sample based on an *a priori* power analysis. Other suggestions include reporting effect sizes (e.g., Cohen's *d*) and confidence intervals to convey more information about the magnitude of effects relative to variance and how close the results are to being determined significant. Additional options include reporting the power of the tests performed or the sample size needed to determine significance for a given effect size. Additionally, meta-analysis—combining effects across multiple studies, even those that are nonsignificant—can provide more powerful and reliable assessments of relations among variables.

NORMAL DISTRIBUTION

The normal distribution, which is also called a Gaussian distribution, bell curve, or normal curve, is commonly known for its bell shape (see Figure 1) and is defined by a mathematical formula. It is a member of families of distributions such as exponential, monotone likelihood ratio, Pearson, stable, and symmetric power. Many biological, physical, and psychological measurements, as well as measurement errors, are thought to

Figure 1 The Normal Distribution

approximate normal distributions. It is one of the most broadly used distributions to describe continuous variables.

The normal curve has played an essential role in statistics. Consequently, research and theory have grown and evolved because of the properties of the normal curve. This entry first describes the characteristics of the normal distribution, followed by a discussion of its applications. Lastly, this entry gives a brief history of the normal distribution.

Characteristics of the Normal Distribution

The normal distribution has several properties, including the following:

- The curve is completely determined by the mean (average) and the standard deviation (the spread about the mean, or girth).
- The mean is at the center of this symmetrical curve (which is also the peak or maximum ordinate of the curve).
- The distribution is unimodal; the mean, median, and mode are the same.
- The curve is asymptotic. Values trail off symmetrically from the mean in both directions, indefinitely (the tails never touch the x axis) and form the two tails of the distribution.
- The curve is infinitely divisible.
- The skewness and kurtosis are both zero.

Different normal density curves exist because a normal distribution is determined by the mean and the standard deviation. Figure 2 presents three normal distributions, one with a mean of 100 and a standard deviation of 20, another normal distribution with a mean of 100 and a standard deviation of 40, and a normal distribution with a mean of 80 and a standard deviation of 20. The curves differ with respect to their spread and their height. There can be an unlimited

Figure 2 Examples of Three Different Normal Distributions

number of normal distributions because there are an infinite number of means and standard deviations, as well as combinations of those means and standard deviations.

Although sometimes labeled as a “bell curve,” the curve does not always resemble a bell shape (e.g., the distribution with a mean of 100 and standard deviation of 40 is flatter in this instance because of the scale being used for the x and y axes). Also, not all bell-shaped curves are normal distributions. What determines whether a curve is a normal distribution is not dependent on its appearance but on its mathematical function.

The normal distribution is a mathematical curve defined by the probability density function (PDF):

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2 / 2\sigma^2},$$

where $f(x)$ = the density of the function or the height of the curve (usually plotted on the y axis) for a particular variable x (usually plotted on the x axis) with a normal distribution

- σ = standard deviation of the distribution
- π = the constant 3.1416
- e = base of Napierian logarithms, 2.7183
- μ = mean of the distribution

This equation dictates the shape of the normal distribution. Normal distributions with the same mean and standard deviation would be identical in form. The curve is symmetrical about its mean because $(x - \mu)$ is squared. Furthermore, because the exponent is negative, the more x deviates from the mean (large positive number or large negative number), $f(x)$ becomes very small, infinitely small but never zero. This explains why the tails of the distribution would never touch the x axis.

The total area under the normal distribution curve equals one (100%). Mathematically, this is represented by the following formula:

$$\int_{-\infty}^{+\infty} f(x) dx = 1.$$

A probability distribution of a variable X can also be described by its cumulative distribution function (CDF). The mathematical formula for the CDF is:

$$\begin{aligned} F(x) &= p(X \leq x) = \int_{-\infty}^x f(t) dt \\ &= \frac{1}{\sigma\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{(t-\mu)^2}{2\sigma^2}} dt. \end{aligned}$$

$F(x)$ gives the probability that any randomly chosen variable X , with a normal distribution, is less than or equal to x , the value of interest. The normal CDF curve is presented in Figure 3 along with the normal PDF curve. The value of the CDF at a point on the x axis equals the area of the PDF up to that same value. CDF values range from 0 to 1.

Applications

The term *normal* was coined to reflect that this probability distribution is commonly found and not that other probability distributions are somehow not “normal.” Although at one time it was extolled as the distribution of all traits, it is now recognized that many traits are best described by other distributions. Exponential distributions, Lévy distributions, and Poisson distributions are some examples of the numerous other distributions that exist.

Some variables that can be said to be approximated by the normal curve include height, weight, personality traits, intelligence, and memory. They are approximated because their real distributions would not be identical to those of a normal distribution. For instance, the real distributions of these variables might not be

Figure 3 The Normal CDF and the Normal PDF Curves

Figure 4 An Example of a Normal Curve and a Curve Fitted to the Data

perfectly symmetrical, their curves might bend slightly, and their tails do not go to infinity. (The tails of the normal distribution go to infinity on the x axis. This observation is not possible for the variables mentioned previously; e.g., certain heights for a human being would be impossible.) The normal distribution reflects the best shape of the data. It is an idealized version of the data (see Figure 4), is described by a mathematical function (the PDF), and because many variables are thought to approximate the normal distribution, it can be used as a model to describe the distribution of the data. Thus, it is possible to take advantage of many of the normal curve’s strengths.

One strength of these normal curves is that they all share a characteristic: probabilities can be identified. However, because normal distributions can take on any mean and/or standard deviation, calculations for each normal distribution would be required to determine the area or probability for a given score or the area between two scores. To avoid these lengthy calculations, the values are converted to standard scores (also called standard units or z scores). Many statistics textbooks present a table of probabilities that is based on a distribution called the standard normal distribution. The standard normal curve consists of a mean (μ) of zero and a standard deviation (σ) of one. The probabilities for the standard normal distribution have been calculated and are known, and because the values of any normal distribution can be converted to a standard score, the probabilities for each normal curve do not need to be calculated but can be found through their conversion to z scores. The density function of the standard normal distribution is

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-z^2/2}.$$

Figure 5 presents a standard normal curve; 68.27% of the values in a particular data set lie between -1σ and $+1\sigma$, 34.13% lie between the mean and $+1\sigma$, 34.13% lie between the mean and -1σ , 95.45% of the values lie between -2σ and $+2\sigma$, 13.59% of the cases lie between $+1\sigma$ and $+2\sigma$, and 13.59% lie between -2σ and -1σ ($2 \times 13.59\% + (2 \times 34.13\%) = 95.45\%$, and

Figure 5 The Standard Normal Distribution and Its Percentiles

99.97% of all values lie between -3σ and $+3\sigma$. Because 99.97% of all values lie between -3 and $+3$ standard deviations, a value found outside of this range would be rare.

Given that all normal curves share the same mathematical function and have the same area under the curve, variables that are normally distributed can be converted to a standard normal distribution using the following formula:

$$z = \frac{(X - \mu)}{\sigma},$$

where

z = standard score on x and represents how many standard deviations a raw score (x) is above or below the mean

X = score of interest for the normally distributed data

μ = mean for the normally distributed data

σ = standard deviation for the normally distributed data

In standardizing a set of scores, they do not become normal. In other words, the shape of a distribution of scores does not change (i.e., does not become normal) by converting them to z scores.

Once scores are standardized, the percentile (proportion of scores) for a given data point/score can be determined easily. To illustrate, if the average score for an intelligence measure is 100 and the standard deviation is 10, then using the above formula and the table of the area of the standard normal distribution, it is

possible to determine percentages (proportions) of cases that have scored less than 120. First, the calculation of the z score is required:

$$z = \frac{(X - \mu)}{\sigma} = \frac{(120 - 100)}{10} = 2.$$

A z score of $+2$ means that the score of 120 is 2 standard deviations above the mean. To determine the percentile for this z score, this value has to be looked up in a table of standardized values of the normal distribution (i.e., a z table). The value of 2 is looked up in a standard normal-curve areas table (not presented here, but can be found in most statistics textbooks) and the corresponding value of .4772 is found (this is the area between the mean and z value of 2). This means that the probability of observing a score between 100 (the mean in this example) and 120 (the score of interest in this example) is .4772. The standard normal distribution is symmetrical around its mean so 50% of all scores are 100 and less. To determine what proportion of individuals score below 120, the value below 100 has to be added to the value between 100 and 120. Therefore, 50% is added to .4772% resulting in 97.72%. Thus, 97.72% of individuals are expected to score worse than or equal to 120. Conversely, if interested in determining the proportion of individuals who would score better than 120, .4772 would be subtracted from .5 and this would equal .0228, which means that 2.28% of individuals would be expected to score better than or equal to 120.

Should a person wish to know the proportion of people who obtained an IQ between 85 and 95, a series of the previous calculations would have to be conducted. In this example, the z scores for 85 and for 95 would have to be first calculated (assuming the same mean and standard deviation as the previous example):

$$\text{For } 85 : z = \frac{(X - \mu)}{\sigma} = \frac{(85 - 100)}{10} = -1.5.$$

$$\text{For } 95 : z = \frac{(X - \mu)}{\sigma} = \frac{(95 - 100)}{10} = -0.5.$$

The areas under the negative z scores are the same as the areas under the identical positive z -scores because the standard normal distribution is symmetrical about its mean (not all tables present both the positive and negative z scores). In looking up the table for $z = 1.5$ and $z = 0.5$, .4332 and .1915, respectively, are obtained. To determine the proportion of IQ scores between 85 and 95, .1915 has to be subtracted from .4332; $.4332 - .1915 = .2417$, 24.17% of IQ scores are found between 85 and 95.

For both examples presented here, the proportions are estimates based on mathematical calculations and do not represent actual observations. Therefore, in the previous example, it is estimated that 97.72% of IQ scores are expected to be less than or equal to 120, and it is estimated that 24.17% are expected to be found between 85 and 95, but what would actually be observed might be different.

The normal distribution is also important because of its numerous mathematical properties. Assuming that the data of interest are normally distributed allows researchers to apply different calculations that can only be applied to data that share the characteristics of a normal curve. For instance, many scores such as percentiles, t scores (scores that have been converted to standard scores and subsequently modified such that their mean is 50 and standard deviation is 10), and stanines (scores that have been changed to a value from 1 to 9 depending on their location in the distribution; e.g., a score found in the top 4% of the distribution is given a value of 9, a score found in the middle 20% of the distribution is given a value of 5) are calculated based on the normal distribution. Many statistics rely on the normal distribution as they are based on the assumption that directly observable scores are normally distributed or have a distribution that approximates normality. Some statistics that assume the variables under study are normally distributed include t , F , and χ^2 . Furthermore, the normal distribution can be used as an approximation for some other distributions.

To determine whether a given set of data follows a normal distribution, examination of skewness and kurtosis, the Probability-Probability (P-P) plot, or results of normality tests such as the Kolmogorov-Smirnov test, Lilliefors test, and the Shapiro-Wilk test can be conducted. If the data do not reflect a normal distribution, then the researcher has to determine whether a few outliers are influencing the distribution of the data, whether data transformation will be necessary, or whether nonparametric statistics will be used to analyze the data, for instance.

Many measurements (latent variables) and phenomena are assumed to be normally distributed (and thus can be approximated by the normal distribution). For instance, intelligence, weight, height, abilities, and personality traits can each be said to follow a normal distribution. However, realistically, researchers deal with data that come from populations that do not perfectly follow a normal distribution, or their distributions are not actually known. The Central Limit Theorem (also known as the second fundamental theorem of probability) partly takes care of this problem. One important element of the Central Limit Theorem states that when

the sample size is large, the sampling distribution of the sample means will approach the normal curve even if the population distribution is not normal. This allows researchers to be less concerned about whether the population distributions follow a normal distribution or not.

These descriptions and applications apply to the univariate normal distribution (i.e., the normal distribution of a single variable). When two (bivariate normal distribution) or more variables are considered, the multivariate normal distribution is important for examining the relation of those variables and for using multivariate statistics.

Whether many variables are actually normally distributed is a point of debate for many researchers. For instance, the view that certain personality traits are normally distributed can never be observed, as the constructs are not actually measured. Many variables are measured using discrete rather than continuous scales. Furthermore, large sample sizes are not always obtained, thus the normal curve might not actually fit well for those data.

History of the Normal Distribution

The first known documentation of the normal distribution was written by Galileo in the 17th century in his description of random errors found in measurements by astronomers. Abraham de Moivre is credited with its first appearance in his publication of an article in 1733. Pierre Simon de Laplace developed the first general Central Limit Theorem in the early 1800s (an important element in the application of the normal distribution) and described the normal distribution. Carl Friedrich Gauss independently discovered the normal curve and its properties at around the same time as de Laplace and was interested primarily in its application to errors of observation in astronomy. It was consequently extensively used for describing errors. Adolphe Quetelet extended the use of the normal curve beyond errors, believing it could be used to describe phenomena in the social sciences, not just physics. Sir Francis Galton in the late 19th century extended Quetelet's work and applied the normal curve to other psychological measurements.

NORMALITY ASSUMPTION

The normal distribution (also called the Gaussian distribution: named after Johann Gauss, a German scientist and mathematician who justified the least squares method in 1809) is the most widely used family of statistical distributions on which many statistical tests are based. Many measurements of physical and psychological phenomena can be approximated by the normal distribution and, hence, the widespread utility of the distribution. In many areas of research, a sample is identified on which measurements of particular phenomena are made. These measurements are then statistically tested, via hypothesis testing, to determine whether the observations are different because of chance. Assuming the test is valid, an inference can be made about the population from which the sample is drawn.

Hypothesis testing involves assumptions about the underlying distribution of the sample data. Three key assumptions, in the order of importance, are independence, common variance, and normality. The term *normality assumption* arises when the researcher asserts

that the distribution of the data follows a normal distribution. Parametric and nonparametric tests are commonly based on the same assumptions with the exception being nonparametric tests do not require the normality assumption.

Independence refers to the correlation between observations of a sample. For example, if you could order the observations in a sample by time, and observations that are closer together in time are more similar and observations further apart in time are less similar, then we would say the observations are not independent but correlated or dependent on time. If the correlation between observations is positive, then the Type I error is inflated (Type I error level is the probability of rejecting the null hypothesis when it is true and is traditionally defined by alpha and set at .05). If the correlation is negative, then Type I error is deflated. Even modest levels of correlation can have substantial impacts on the Type I error level (for a correlation of .2, the alpha is .11, whereas for a correlation of .5, the alpha level is .26). Independence of observations is difficult to assess. With no formal statistical tests widely in use, knowledge of the substantive area is paramount and a thorough understanding of how the data were generated is required for valid statistical analysis and interpretation to be undertaken.

Common variance (often referred to as homogeneity of variance) refers to the concept that the variance of all samples drawn has similar variability. For example, if you were testing the difference in height between two samples of people, one from Town A and the other from Town B, the test assumes that the variance of height in Town A is similar to that of Town B. In 1953, G. E. P. Box demonstrated that for even modest sample sizes, most tests are robust to this assumption, and differences of up to 3-fold in variance do not greatly affect the Type I error level. Many statistical tests are available to ascertain whether the variances are equal among different samples (including the Bartlett–Kendall test, Levene’s test, and the Brown–Forsythe test). These tests for the homogeneity of variance are sensitive to normality departures, and as such they might indicate that the common variance assumption does not hold, although the validity of the test is not in question.

Although it is the least important of the assumptions when considering hypothesis testing, the normality assumption should not be ignored. Many statistical tests and methods employed in research require that a variable or variables be normally distributed. Aspects of normality include the following: (a) that the possible values of the quantity being studied can vary from negative infinity to positive infinity; (b) that there will be symmetry in the data, in that observed values will

fall with equal probability above and below the true population mean value, as a process of unbiased, random variability; and (c) the width or spread of the distribution of observed values around the true mean will be determined by the standard deviation of the distribution (with predictable values falling within or outside the bounds defined by multiples of the true distribution standard deviation). Real-world data might behave differently from the normal distribution for several reasons. Many physiological and behavioral variables cannot truly have infinite range, and distributions might be truncated at true zero values. Skewness (asymmetry), or greater spread in observed values than predicted by the standard deviation, might also result in situations where the distribution of observed values is not determined exclusively by random variability, and it also might be a result of unidentified systematic influences (or unmeasured predictors of the outcome).

The statistical tests assume that the data follow a normal distribution to preserve the tests' validity. When undertaking regression models, the normality assumption applies to the error term of the model (often called the residuals) and not the original data and, hence, it is often misunderstood in this context. It should be noted that the normality assumption is sufficient, but not necessary, for the validity of many hypothesis tests. The remainder of this entry focuses on the assessment of normality and the transformation of data that are not normally distributed.

Assessing Normality

A researcher can assess for the normality of variables in several ways. To say a variable is normally distributed indicates that the distribution of observations for that variable follows the normal distribution. So in essence, if you examined the distribution graphically, it would look similar to the typical bell-shaped normal curve. A histogram, a box-and-whisker plot, or a normal quartile plot (often called a Q-Q plot) can be created to inspect the normality of the data visually. With many data analysis packages, a histogram can be requested with the normal distribution superimposed to aid in this assessment. Other standard measures of distribution exist and include skewness and kurtosis. Skewness refers to the symmetry of the distribution, in which right-skewed distributions have a long tail pointing to the right and left-skewed distributions have a long tail pointing to the left. Kurtosis refers to peakedness of the distribution.

A box-and-whisker plot is created with five numeric summaries of the variables including the minimum value, the lower quartile, the median, the upper

quartile, and the maximum value. The box is formed by the lower and upper quartiles bisected by the median. Whiskers are formed on the box plot by drawing a line from the lowest edge of the box (lower quartile) to the minimum value and the highest edge of the box (upper quartile) to the maximum value. If the variable has a normal distribution, the box will be bisected in the middle by the median, and both whiskers will be of equal length.

A normal quartile plot compares the spacing of the data with that of the normal distribution. If the data being examined are approximately normal, then more observations should be clustered around the mean and only a few observations should exist in each of the tails. The vertical axis of the plot displays the actual data whereas the horizontal axis displays the quartiles from the normal distribution (expected z scores). If the data are normally distributed, the resulting plot will form a straight line with a slope of 1. If the line demonstrates an upward bending curve, the data are right skewed, whereas if the line demonstrates a downward bending curve, the data are left skewed. If the line has an S-shape, it indicates that the data are kurtotic.

Several common statistical tests were designed to assess normality. These would include, but are not limited to, the Kolmogorov–Smirnov, the Shapiro–Wilk, the Anderson–Darling, and the Lilliefors test. In each case, the test calculates a test statistic under the null hypothesis that the sample is drawn from a normal distribution. If the associated p value for the test statistic is greater than the selected alpha level, then one does not reject the null hypothesis that the data were drawn from a normal distribution. Some tests can be modified to test samples against other statistical distributions. The Shapiro–Wilk and the Anderson–Darling tests have been noted to perform better with small sample sizes. With all the tests, small deviations from normality can lead to a rejection of the null hypothesis and therefore should be used and interpreted with caution.

When a violation of the normality assumption is observed, it might be a sign that a better statistical model can be found. So, exploring why the assumption is violated might be fruitful. Non-normality of the error term might indicate that the resulting error is greater than expected under the assumption of true random variability and (especially when the distribution of the data are asymmetrical) might suggest that the observations come from more than one “true” underlying population. Additional variables could be added to the model (or the study) to predict systematically observed values not yet in the model, thereby moving more information to the linear predictor. Similarly, non-normality might reflect that variables in the model are incorrectly

specified (such as assuming there is a linear association between a continuous predictor variable and the outcome).

Research is often concerned with more than one variable, and with regression analysis or statistical modeling, the assumption is that the combination of variables under study follows a multivariate normal distribution. There are no direct tests for multivariate normality, and as such, each variable under consideration is considered individually for normality. If all the variables under study are normally distributed, then another assumption is made that the variables combined are multivariate normal. Although this assumption is made, it is not always the case that variables are normal individually and collectively. Note that when assessing normality in a regression modeling situation, the assessment of normality should be undertaken with the error term (residuals).

Note of Caution: Small Sample Sizes

When assessing normality with small sample sizes (samples with less than approximately 50 observations), caution should be exercised. Both the visual aids (histogram, box-and-whisker plot, and normal quartile plot) and the statistical tests (Kolmogorov–Smirnov, Shapiro–Wilk, Anderson–Darling, and Lilliefors’s test) can provide misleading results. Departures from normality are difficult to detect with small sample sizes, largely because of the power of the test. The power of the statistical tests decreases as the significance level is decreased (as the statistical test is made more stringent) and increases as the sample size increases. So, with small sample sizes, the statistical tests will nearly always indicate acceptance of the null hypothesis even though departures from normality could be large. Likewise, with large sample sizes, the statistical tests become powerful, and often minor inconsequential departures from normality would lead the researcher to reject the null hypothesis.

What to Do If Data Are Not Normally Distributed

If, after assessment, the data are not normally distributed, a transformation of the non-normal variables might improve normality. If after transformation the variable meets the normality assumption, the transformed variable can be substituted in the analysis. Interpretation of a transformed variable in an analysis needs to be undertaken with caution as the scale of the variable will be related to the transformation and not the original units.

Based on Frederick Mosteller and John Tukey’s Ladders of Power, if a researcher needs to remove right skewness from the data, then he or she moves “down” the ladder of power by applying a transformation smaller than 1, such as the square root, cube root, logarithm, or reciprocal. If the researcher needs to remove left skewness from the data, then he or she moves “up” the ladder of power by applying a transformation larger than 1 such as squaring or cubing.

Many analysts have tried other means to avoid non-normality of the error term including categorizing the variable, truncating or eliminating extreme values from the distribution of the original variable, or restricting the study or experiment to observations within a narrower range of the original measure (where the residuals observed might form a “normal” pattern). None of these are ideal as they might affect the measurement properties of the original variable and create problems with bias of estimates of interest and/or loss of statistical power in the analysis.

NORMALIZING DATA

Researchers often want to compare scores or sets of scores obtained on different scales. For example, how do we compare a score of 85 in a cooking contest with a score of 100 on an IQ test? To do so, we need to “eliminate” the unit of measurement; this operation means to *normalize* the data. There are two main types of normalization. The first type of normalization originates from linear algebra and treats the data as a *vector* in a multidimensional space. In this context, to normalize the data is to transform the data vector into a new vector whose *norm* (i.e., length) is equal to one. The

second type of normalization originates from statistics and eliminates the unit of measurement by transforming the data into new scores with a mean of 0 and a standard deviation of 1. These transformed scores are known as z scores.

Normalization to a Norm of One

The Norm of a Vector

In linear algebra, the *norm* of a vector measures its *length*, which is equal to the Euclidean distance of the endpoint of this vector to the origin of the vector space. This quantity is computed (from the Pythagorean theorem) as the square root of the sum of the squared elements of the vector. For example, consider the following data vector denoted $\mathbf{y}$:

$$\mathbf{y} = \begin{bmatrix} 35 \\ 36 \\ 46 \\ 68 \\ 70 \end{bmatrix}. \quad (1)$$

The norm of vector $\mathbf{y}$ is denoted $\|\mathbf{y}\|$ and is computed as

$$\begin{aligned} \|\mathbf{y}\| &= \sqrt{35^2 + 36^2 + 46^2 + 68^2 + 70^2} \\ &= \sqrt{14,161} = 119. \end{aligned} \quad (2)$$

Normalizing With the Norm

To normalize $\mathbf{y}$, we divide each element by $\|\mathbf{y}\| = 119$. The normalized vector, denoted $\tilde{\mathbf{y}}$, is equal to

$$\tilde{\mathbf{y}} = \begin{bmatrix} \frac{35}{119} \\ \frac{36}{119} \\ \frac{46}{119} \\ \frac{68}{119} \\ \frac{70}{119} \end{bmatrix} = \begin{bmatrix} 0.2941 \\ 0.3025 \\ 0.3866 \\ 0.5714 \\ 0.5882 \end{bmatrix}. \quad (3)$$

The norm of vector $\tilde{\mathbf{y}}$ is now equal to one:

$$\begin{aligned} \|\tilde{\mathbf{y}}\| &= \sqrt{0.2941^2 + 0.3025^2 + 0.3866^2 + 0.5714^2 + 0.5882^2} \\ &= \sqrt{1} = 1. \end{aligned} \quad (4)$$

Normalization Using Centering and Standard Deviation: z Scores

The Standard Deviation of a Set of Scores

Recall that the standard deviation of a set of scores expresses the dispersion of the scores around their mean. A set of N scores, each denoted Y_n , whose mean is equal to M , has a standard deviation denoted $\hat{S}$, which is computed as

$$\hat{S} = \frac{\sum (Y_n - M)^2}{N - 1}. \quad (5)$$

For example, the scores from vector $\mathbf{y}$ (see Equation 4) have a mean of 51 and a standard deviation of

$$\begin{aligned} \hat{S} &= \sqrt{\frac{(35 - 51)^2 + (36 - 51)^2 + (46 - 51)^2 + (68 - 51)^2 + (70 - 51)^2}{5 - 1}} \\ &= \frac{1}{2} \sqrt{(-16)^2 + (-15)^2 + (-5)^2 + 17^2 + 19^2} \\ &= 17. \end{aligned} \quad (6)$$

z Scores: Normalizing With the Standard Deviation

To normalize a set of scores using the standard deviation, we divide each score by the standard deviation of this set of scores. In this context, we almost always subtract the mean of the scores from each score prior to dividing by the standard deviation. This normalization is known as z scores. Formally, a set of N scores each denoted Y_n and whose mean is equal to M and whose standard deviation is equal to $\hat{S}$ is transformed in z scores as

$$z_n = \frac{Y_n - M}{\hat{S}}. \quad (7)$$

With elementary algebraic manipulations, it can be shown that a set of z scores has a mean equal of zero and a standard deviation of one. Therefore, z scores constitute a unit-free measure that can be used to compare observations measured with different units.

Example

For example, the scores from vector $\mathbf{y}$ (see Equation 1) have a mean of 51 and a standard deviation of 17. These scores can be transformed into the vector $\mathbf{z}$ of z scores as

$$\mathbf{z} = \begin{bmatrix} \frac{35-51}{17} \\ \frac{36-51}{17} \\ \frac{46-51}{17} \\ \frac{68-51}{17} \\ \frac{70-51}{17} \end{bmatrix} = \begin{bmatrix} -\frac{16}{17} \\ -\frac{15}{17} \\ -\frac{5}{17} \\ \frac{17}{17} \\ \frac{19}{17} \end{bmatrix} = \begin{bmatrix} -0.9412 \\ -0.8824 \\ -0.2941 \\ 1.0000 \\ 1.1176 \end{bmatrix}. \quad (8)$$

The mean of vector $\mathbf{z}$ is now equal to zero, and its standard deviation is equal to one.

NUISANCE PARAMETERS

Nuisance parameters are elements in statistical models that are not immediately of interest to a researcher but that are important to specify in order to define the primary effect of interest. For example, if we consider the variance, σ^2 , and the mean, μ , and the mean is our primary interest, then variance might be the nuisance parameter. Nuisance parameters are often variances; however, this is not a strict rule. In general terms, any parameter that is used on the analysis of another can be considered a nuisance parameter.

Thus, the nuisance parameter is a parameter of secondary interest, which is used to account for the estimated value of a parameter of primary interest. A simple example to illustrate the issue is the following: Assume that we want to determine if there are gender differences in learning foreign language skills. Defining a target group, such as university students, and obtaining a sample size to provide enough evidence, we try to

measure the means for both male and female students. If we calculate the variance before determining the means, then the variance is a nuisance parameter.

Theoretically speaking, the treatment of nuisance parameters can be quite similar to Bayesian approaches. Despite model uncertainty, when the focus is on parameter estimation, Bayesian analysis allows the model indicator to be treated as a nuisance parameter. It attempts to derive the partition of the likelihood function, which is divided into components providing information about both the parameters of interest and the nuisance parameters (included in the model). Based on frequentist theory, once these partitions are achieved, then it is easy to develop a general estimation approach by using the nuisance parameters.

Generally, the variance is included as continuous data. Three common cases of other parameters of interest are treatment effect, power, and sample size. The reason that a sample size is selected is to provide evidence that a desired effect of interest can be detected for some fixed level of power and sample size. The power analysis is conducted to determine the power of a study with a fixed sample size and detectable effect of interest. In case of a small effect of interest, then a large sample size will be required to have a high probability of detecting the effect at a specified level of power. The preferred level of power is 80% to 90% for planning purposes.

As an example, consider the 2014 study by Yang Ning and colleagues, which involved reducing sensitivity to nuisance parameters in pseudo-likelihood functions. They considered the following model:

$$Y = X\gamma + \epsilon, \epsilon \sim N(0, \emptyset),$$

where:

- Y is an $n \times 1$ vector of response variables,
- X is an $n \times q$ design matrix,
- $\emptyset$ is an $n \times n$ matrix indexed by an unknown parameter of interest $\emptyset$ with dimension p , and
- γ is the nuisance parameter.

In general, as a standard procedure, γ is estimated by the conventional least square estimator $\hat{\gamma} = (X^T X)^{-1} X^T Y$, and inference about $\emptyset$ is based on $L\hat{\gamma}$, $\hat{\gamma}$, where $L\hat{\gamma}$, $\hat{\gamma}$ is the log likelihood based on data $Y = y$. The pseudo-likelihood approach is used mostly in the field of genetic epidemiology.

Furthermore, Stephen Senn in his 2012 article mentioned “the nuisance parameter nuisance,” which has to do with the debate about the terms used in a model being a univariate error, or disturbance. Senn uses “univariate” in quotation marks to indicate the ongoing

discussion related to the term. The disturbance term is widely discussed, with questions being raised about other multivariate speculations. Related speculations raised by various researchers include “if the variance is identical for each disturbance term,” “if the disturbance terms are independent,” or “if the disturbance terms are normally distributed.”

NUISANCE VARIABLE

A nuisance variable is an unwanted variable that is typically correlated with the hypothesized independent variable within an experimental study but is typically of no interest to the researcher. It might be a characteristic of the participants under study or any unintended influence on an experimental manipulation. A nuisance variable causes greater variability in the distribution of a sample's scores and affects all the groups measured within a given sample (e.g., treatment and control).

Whereas the distribution of scores changes because of the nuisance variable, the location (or the measure of central tendency) of the distribution remains the same, even when a nuisance variable is present. Figure 1 is an example using participants' scores on a measure that assesses accuracy in responding to simple math problems. Note that the mean is 5.00 for each of the two samples, yet the distributions are actually different. The range for the group without the nuisance variable is 4, with a standard deviation of 1.19. However, the range for the group with the nuisance variable is 8, with a standard deviation of 2.05.

For the first distribution, participants' math accuracy scores are relatively similar and cluster around the mean of the distribution. There are fewer very high scores and fewer very low scores when compared with the distribution in which the nuisance variable is operating. Within the distribution with the nuisance variable, a wider spread is observed, and there are fewer scores at the mean than in the distribution without the nuisance variable.

Figure 1 Frequency Distributions With and Without Nuisance Variable

Notes: (a) Without nuisance variable ($N = 240$). (b) With nuisance variable ($N = 240$).

In an experimental study, a nuisance variable affects within-group differences for both the treatment group and the control group. When a nuisance variable is present, the spread of scores for each group increases, which makes it more difficult to observe effects that might be attributed to the independent variable (i.e., the treatment effect). When there is greater spread within the distributions of the treatment group and the control group, there is more overlap between the two. This makes the differences between the two groups less clear and distinct.

Figure 2 is an example using treatment and control groups, in which the independent variable is an extra-curricular math tutoring program and is received only by the treatment group. Both samples are tested after the administration of the math tutoring program on measures of math accuracy. In this case, a nuisance variable might be the participant's level of anxiety, but it could just as easily be an external characteristic of the experiment, such as the amount of superfluous noise in the room where the measure of math accuracy is being administered. In considering the effects of the nuisance variable, the distributions of the two groups within the sample might look similar to that in Figure 2.

In the distribution without the nuisance variable, the variation in participants' anxiety is reduced or eliminated, and it is clear that the differences in participants' observed math scores are, more than likely, caused by

the manipulation of the independent variable only (i.e., the administration of a math tutorial to the treatment group but not the control group).

In the distribution with the nuisance variable, if there is greater variation in the amount of anxiety experienced by participants in both the treatment group and the control group, and if the participant's anxiety influences his or her math accuracy, then greater variation will be observed in the distributions of participants' scores on the measure of math accuracy. For example, someone who performs poorly when feeling anxious might have scored a 4 on math accuracy if this nuisance variable had been removed. However, now that he or she is feeling anxious, his or her score might drop to a 2. Alternatively, others might perform better when experiencing anxiety. In this case, a participant might have originally scored a 6 if he or she felt no anxiety but actually scored an 8 because of the anxiety. In this case, with the nuisance variable present, it becomes more difficult to detect whether statistically significant differences exist between the two groups in question because of the greater variance within the groups.

Researchers aim to control the influences of nuisance variables methodologically and/or statistically, so that differences in the dependent variable might be attributed more clearly to the manipulation of the independent variable. In exercising methodological control,

Figure 2 Frequency Distributions of Treatment and Control Groups With and Without Nuisance Variable

Notes: (a) Without nuisance variable. (b) With nuisance variable.

a researcher might choose only those participants who do not experience anxiety when taking tests of this nature. This would eliminate any variation in anxiety and, in turn, any influence that anxiety might have on participants' math accuracy scores. In exercising statistical control, a researcher might employ regression techniques to control for any variation caused by a nuisance variable. However, in this case, it becomes important to specify and measure potential nuisance variables before and during the experiment. In the example used previously, participants could be given a measure of anxiety along with the measure of math accuracy. Multiple regression models might then be used to statistically control for the influence of anxiety on math accuracy scores alongside any experimental treatment that might be administered.

The term *nuisance variable* is often used alongside the terms *extraneous* and *confounding* variable. Whereas an extraneous variable influences differences observed between groups, a nuisance variable influences differences observed within groups. By eliminating the effects of nuisance variables, the tests of the null hypothesis become more powerful in uncovering group differences.

NULL HYPOTHESIS

In many sciences, including ecology, medicine, and psychology, null hypothesis significance testing (NHST) is the primary means by which the numbers comprising the data from some experiment are translated into conclusions about the question(s) that the experiment was designed to address. This entry first provides a brief description of NHST, and within the context of NHST, it defines the most common incarnation of a null hypothesis. Second, this entry sketches other less common forms of a null hypothesis. Third, this entry

articulates several problems with using null hypothesis-based data analysis procedures.

Null Hypothesis Significance Testing and the Null Hypothesis

Most experiments entail measuring the effect(s) of some number of independent variables on some dependent variable.

An Example Experiment

In the simplest sort of experimental design, one measures the effect of a single independent variable, such as the amount of information held in short-term memory on a single dependent variable and the reaction time to scan through this information. To pick a somewhat arbitrary example from cognitive psychology, consider what is known as a *Sternberg experiment*, in which a short sequence of memory digits (e.g., “34291”) is read to an observer who must then decide whether a single, subsequently presented test digit was part of the sequence. Thus for instance, given the memory digits above, the correct answer would be “yes” for a test digit of “2” but “no” for a test digit of “8.” The independent variable of “amount of information held in short-term memory” can be implemented by varying *set size*, which is the number of memory digits presented: In different conditions, the set size might be, say, 1, 3, 5 (as in the example), or 8 presented memory digits. The number of different set sizes (here 4) is more generally referred to as the number of *levels* of the independent variable. The dependent variable is the reaction time measured from the appearance of the test digit to the observer's response. Of interest in general is the degree to which the magnitude of the dependent variable (here, reaction time) depends on the level of the independent variable (here set size).

Sample and Population Means

Typically, the principal dependent variable takes the form of a *mean*. In this example, the mean reaction time for a given set size could be computed across observers. Such a computed mean is called a *sample mean*, referring to its having been computed across an observed sample of numbers. A sample mean is construed as an estimate of a corresponding *population mean*, which is what the mean value of the dependent variable would be if all observers in the relevant population were to participate in a given condition of the experiment. Generally, conclusions from experiments are meant to apply to population means. Therefore, the

measured sample means are only interesting insofar as they are estimates of the corresponding population means.

Notationally, the sample means are referred to as the M_j s, whereas the population means are referred to as the μ_j s. For both sample and population means, the subscript j indexes the level of the independent variable; thus, in our example, M_2 would refer to the observed mean reaction time of the second set-size level (i.e., set size = 3) and likewise, μ_2 would refer to the corresponding, unobservable population mean reaction time corresponding to set size = 3.

Two Competing Hypotheses

NHST entails establishing and evaluating two mutually exclusive and exhaustive hypotheses about the relation between the independent variable and the dependent variable. Usually, and in its simplest form, the null hypothesis (abbreviated H_0) is that the independent variable has *no effect* on the dependent variable, whereas the alternative hypothesis (abbreviated H_1) is that the independent variable has *some effect* on the dependent variable. Note an important asymmetry between a null hypothesis and an alternative hypothesis: A null hypothesis is an *exact* hypothesis, whereas an alternative hypothesis is an *inexact* hypothesis. By this it is meant that a null hypothesis can be correct in only one way, viz, the μ_j s are all equal to one another, whereas there are an infinite number of ways in which the μ_j s can be different from one another (i.e., an infinite number of ways in which an alternative hypothesis can be true).

Decisions Based on Data

Having established a null and an alternative hypothesis that are mutually exclusive and exhaustive, the experimental data are used to—roughly speaking—decide between them. The technical manner by which one makes such a decision is beyond the scope of this entry, but two remarks about the process are appropriate here.

1. A major ingredient in the decision is the variability of the M_j s. To the degree that the M_j s are close to one another, evidence ensues for possible equality of the μ_j s and, ipso facto, validity of the null hypothesis. Conversely, to the degree that the M_j s differ from one another, evidence ensues for associated differences among the μ_j s and, ipso facto, validity of the alternative hypothesis.
2. The asymmetry between the null hypothesis (which is exact) and the alternative hypothesis (which is

inexact) sketched previously implies an associated asymmetry in conclusions about their validity. If the M_j s differ sufficiently, one “rejects the null hypothesis” in favor of accepting the alternative hypothesis. However, if the M_j s do not differ sufficiently, one does not “accept the null hypothesis” but rather one “fails to reject the null hypothesis.” The reason for the awkward, but logically necessary, wording of the latter conclusion is that, because the alternative hypothesis is inexact, one cannot generally distinguish a genuinely true null hypothesis on the one hand from an alternative hypothesis entailing small differences among the μ_j s on the other hand.

Multifactor Designs: Multiple Null Hypothesis–Alternative Hypothesis Pairings

So far, this entry has described a simple design in which the effect of a single independent variable on a single dependent variable is examined. Many, if not most experiments, use multiple independent variables and are known as *multifactor designs* (“factor” and “independent variable” are synonymous). Continuing with the example experiment, imagine that in addition to measuring the effects of set size on reaction time in a Sternberg task, one also wanted to measure simultaneously the effects on reaction time of the test digit’s visual contrast (informally, the degree to which the test digit stands out against the background). One might then *factorially combine* the four levels of set size (now called “factor 1”) with, say, two levels, “high contrast” and “low contrast,” of test-digit contrast (now called “factor 2”). Combining the four set-size levels with the two test-digit contrast levels would yield $4 \times 2 = 8$ separate conditions. Typically, three independent NHST procedures would then be carried out, entailing three null hypothesis–alternative hypothesis pairings. They are as follows:

1. For the set size main effect:

H_0 : Averaged over the two test-digit contrasts, there is no set-size effect

H_1 : Averaged over the two test-digit contrasts, there is a set-size effect

2. For the test-digit contrast main effect:

H_0 : Averaged over the four set sizes, there is no test-digit contrast effect

H_1 : Averaged over the four set sizes, there is a test-digit contrast effect

3. For set-size by test-digit contrast interaction:

Two independent variables are said to *interact* if the effect of one independent variable depends on the level of the other independent variable. As with the main

effects, interaction effects are immediately identifiable with respect to the M_j s; however, again as with main effects, the goal is to decide whether interaction effects exist with respect to the corresponding μ_j s. As with the main effects, NHST involves pitting a null hypothesis against an associated alternative hypothesis.

H_0 : With respect to the μ_j s, set size and test-digit contrast do not interact.

H_1 : With respect to the μ_j s, set size and test-digit contrast do interact.

The logic of carrying out NHST with respect to interactions is the same as the logic of carrying out NHST with respect to main effects. In particular, with interactions as with main effects, one can reject a null hypothesis of no interaction, but one cannot accept a null hypothesis of no interaction.

Non-Zero-Effect Null Hypotheses

The null hypotheses described above imply “no effect” of one sort or another—either no main effect of some independent variable or no interaction between two independent variables. This kind of no-effect null hypothesis is by far the most common null hypothesis to be found in the literature. Technically however, a null hypothesis can be any *exact hypothesis*; that is, the null hypothesis of “all μ_j s are equal to one another” is but one special case of what a null hypothesis can be.

To illustrate another form, let us continue with the first, simpler Sternberg-task example (set size is the only independent variable), but imagine that prior research justifies the assumption that the relation between set size and reaction time is linear. Suppose also that research with digits has yielded the conclusion that reaction time increases by 35 ms for every additional digit held in short-term memory; that is, if reaction time were plotted against set size, the resulting function would be linear with a slope of 35 ms.

Now, let us imagine that the Sternberg experiment is done with words rather than digits. One could establish the null hypothesis that “short-term memory processing proceeds at the same rate with words as it does with digits” (i.e., that the slope of the reaction time versus set-size function would be 35 ms for words just as it is known to be with digits). The alternative hypothesis would then be “for words, the function’s slope is anything other than 35 ms.” Again, the fundamental distinction between a null and alternative hypothesis is that the null hypothesis is exact (35 ms/

digit), whereas the alternative hypothesis is inexact (anything else). This distinction would again drive the asymmetry between conclusions, which were articulated previously: a particular pattern of empirical results could logically allow “rejection of the null hypothesis”;—that is, “acceptance of the alternative hypothesis” but not “acceptance of the null hypothesis.”

Problems With Null Hypothesis Significance Testing

No description of NHST in general, or a null hypothesis in particular, is complete without at least a brief account of the serious problems that accrue when NHST is the sole statistical technique used for making inferences about the μ s from the M_j s. Briefly, three major problems involving a null hypothesis as the centerpiece of data analysis are discussed below.

A Null Hypothesis Cannot Be Literally True

In most sciences, it is almost a self-evident truth that any independent variable must have some effect, even if small, on any dependent variable. This is certainly true in psychology. In the Sternberg task, to illustrate, it is simply implausible that set size would have literally *zero* effect on reaction time (i.e., that the μ_j s corresponding to the different set sizes would be *identical* to an infinite number of decimal places). Therefore, rejecting a null hypothesis—which, as noted, is the only strong conclusion that is possible within the context of NHST—tells the investigator nothing that the investigator should have been able to realize was true beforehand. Most investigators do not recognize this, but that does not prevent it from being so.

Human Nature Makes Acceptance of a Null Hypothesis Almost Irresistible

Earlier, this entry detailed why it is logically forbidden to accept a null hypothesis. However, human nature dictates that people do not like to make weak yet complicated conclusions such as “We fail to reject the null hypothesis.” Scientific investigators, generally being humans, are not exceptions. Instead, a “fail to reject” decision, which is dutifully made in an article’s results section, often morphs into “the null hypothesis is true” in the article’s discussion and conclusions sections. This kind of sloppiness, although understandable, has led to no end of confusion and general scientific mischief within numerous disciplines.

Null Hypothesis Significance Testing Emphasizes Barren, Dichotomous Conclusions

Earlier, this entry described that the pattern of population means—the relations among the unobservable μ_j s—is of primary interest in most scientific experiments and that the observable M_j s are estimates of the μ_j s. Accordingly, it should be of great interest to assess how good are the M_j s as estimates of the μ_j s. If, to use an extreme example, the M_j s were perfect estimates of the μ_j s, there would be no need for statistical analysis: The answers to any question about the μ_j s would be immediately available from the data. To the degree that the estimates are less good, one must exercise concomitant caution in using the M_j s to make inferences about the μ_j s.

None of this is relevant within the process of NHST, which does not in any way emphasize the degree to which the M_j s are good estimates of the μ_j s. In its typical form, NHST allows only a limited assessment of the nature of the μ_j s: Are they all equal or not? Typically, the “no” or “not necessarily no” conclusion that emerges from this process is insufficient to evaluate the totality of what the data might potentially reveal about the nature of the μ_j s.

An alternative that is gradually emerging within several NHST-heavy sciences—an alternative that is common in the natural sciences—is the use of *confidence intervals* that assess directly how good is a M_j as an estimate of the corresponding μ_j . Briefly, a confidence interval is an interval constructed around a sample mean that, with some pre-specified probability (typically 95%), includes the corresponding population mean. A glance at a set of plotted M_j s with associated plotted confidence intervals provides immediate and intuitive information about (a) the most likely pattern of the μ_j s and (b) the reliability of the pattern of M_j s as an estimate of the pattern of μ_j s. This in turn provides immediate and intuitive information both about the relatively uninteresting question of whether some null hypothesis is true and about the much more interesting questions of what the pattern of μ_j s actually is and how much belief can be placed in it based on the data at hand.

NUREMBERG CODE

The term *Nuremberg Code* refers to the set of standards for conducting research with human subjects that was developed in 1947 at the end of World War II, in the trial of 23 Nazi doctors and scientists in Nuremberg, Germany, for war crimes that included medical experiments on persons designated as non-German nationals. The trial of individual Nazi leaders by the Nuremberg War Crimes Tribunal, the supranational institution charged with determining justice in the transition to democracy, set a vital precedent for international jurisprudence.

The *Nuremberg Code* was designed to protect the autonomy and rights of human subjects in medical research, as compared with the Hippocratic Oath applied in the therapeutic, paternalistic patient-physician relationship. It is recognized as initiating the modern international human rights movement during social construction of ethical codes, with the Universal Declaration of Human Rights in 1954. Human subjects abuse by Nazi physicians occurred despite German guidelines for protection in experimentation, as noted by Michael Branigan and Judith Boss. Because the international use of prisoners in research had grown during World War II, the Code required that children, prisoners, and patients in mental institutions were not to be used as subjects in experiments. However, it was reinterpreted to expand medical research in the Declaration of Helsinki by the World Medical Association in 1964.

The legal judgment in the Nuremberg trial by a panel of American and European physicians and scientists contained 10 moral, ethical, and legal requirements to guide researchers in experiments with human subjects. These requirements are as follows: (1) voluntary informed consent based on legal capacity and without coercion is essential; (2) research should be designed to produce results for the good of society that are not obtainable by other means; (3) human subjects research should be based on prior animal research; (4) physical and mental suffering must be avoided; (5) no research should be conducted for which death or disabling injury is anticipated; (6) risks should be justified by anticipated humanitarian benefits; (7) precautions and facilities should be provided to protect research subjects against potential injury, disability, or death; (8) research should only be conducted by qualified scientists; (9) the subject should be able to end the study during the research; (10) the scientist should be able to end the research at any stage if potential for injury, disability, or death of the subject is recognized.

Impact on Human Subjects Research

At the time the *Nuremberg Code* was formulated, many viewed it as created in response to Nazi medical experimentation and without legal authority in the United States and Europe. Some American scientists considered the guidelines implicit in their human subjects research, applying to nontherapeutic research in wartime. The informed consent requirement was later incorporated into biomedical research, and physicians continued to be guided by the Hippocratic Oath for clinical research.

Reinterpretation of the *Nuremberg Code* in the Declaration of Helsinki for medical research modified requirements for informed consent and subject recruitment, particularly in pediatrics, psychiatry, and research with prisoners. Therapeutic research was distinguished from nontherapeutic research, and therapeutic privilege was legitimated in the patient-physician relationship.

However, social and biomedical change, as well as the roles of scientists and ethicists in research and technology, led to the creation of an explicitly subjects-centered approach to human rights. This has been incorporated into research in medicine and public health, and in behavioral and social sciences.

Biomedical, Behavioral, and Community Research

With the enactment of federal civil and patient rights legislation, the erosion of public trust, and the extensive criticism of ethical violations and discrimination in the Tuskegee syphilis experiments by the U.S. Public Health Service (1932–1971), biomedical and behavioral research with human subjects became regulated by academic and hospital-based institutional review boards. The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was established in the United States in 1974, with requirements for review boards in institutions supported by the Department of Health, Education and Welfare.

In 1979, the Belmont Report set four ethical principles for human subjects research: (1) beneficence and nonmaleficence, to maximize benefits and minimize risk of harm; (2) respect for autonomy in decision-making and protection of those with limited autonomy; (3) justice, for fair treatment; and (4) equitable distribution of benefits and risks. The Council for International Organizations of Medical Sciences and the World Health Organization formulated *International Ethical Guidelines for Biomedical Research Involving Human Subjects* for research ethics committees in 1982. Yet in 1987, the U.S. Supreme Court refused to endorse the *Nuremberg Code* as binding on all research, and it was not until 1997 that national security research had to be based on informed consent.

Institutional review boards (IRBs) were established to monitor informed consent and avoid risk and exploitation of vulnerable populations. Research organizations and Veterans Administration facilities might be accredited by the Association for Accreditation of Human Research Protection Programs. Although IRBs originated for biomedical and clinical research, their purview extends to behavioral and social sciences. Nancy Shore and colleagues note that public health emphasis on community-based participatory research is shifting focus from protection of individual subjects to ethical relationships with community members and organizations as partners.

Yet global clinical drug trials by pharmaceutical companies and researchers' efforts to limit restrictions on placebo-controlled trials have contributed to the substitution of "Good Clinical Practice Rules" for the Declaration of Helsinki by the U.S. Food and Drug Administration in 2004. The development of rules by regulators and drug industry trade groups and the approval by untrained local ethics committees in

developing countries could diminish voluntary consent and benefits for research subjects.

Subsequent change in application of the *Nuremberg Code* has occurred with the use of prisoners in clinical drug trials, particularly for HIV drugs, according to Branigan and Boss. This practice is illegal for researchers who receive federal support but is legal in some states. The inclusion of prisoners and recruitment of subjects from ethnic or racial minority groups for clinical trials might offer them potential benefits, although it must be balanced against risk and need for justice.

NVivo

NVivo provides software tools that assist researchers who need to manage and analyze qualitative and mixed methods data from the time when they start thinking about a project, through to its completion. NVivo is relevant to the task of research design in two senses: its tools contribute to the design process for a research project, and, if it is to be used also for analysis of qualitative or mixed methods data, then understanding how the software works and planning for its use at the design stage will ensure more efficient and effective use of its tools and an enriched analysis. This entry begins with an overview of NVivo and its capabilities. It then provides a detailed description of the ways in which NVivo can assist in the process of research design. Finally, the entry offers guidance when researchers intend to use NVivo for analysis of qualitative or mixed methods data.

What Is NVivo and What Does It Do?

NVivo is one of several computer programs that are designed for researchers working with qualitative and/or mixed methods data. The tools provided by NVivo help the researcher to

- import, track, and manage varied data sources and information about these sources;
- trace and link ideas associated with or derived from these data sources;
- locate all instances of terms or concepts in a body of data;
- code text or multimedia information for easy retrieval;
- organize codes to build and/or support a conceptual framework for a study;
- query relationships between concepts, themes, or categories within or across different types or sets of data;
- explore relationships between attributes associated with sources (demographics, scores, times) and coded qualitative data from those sources; and
- construct visual models with links to data.

A particular and unique strength of NVivo is that its data management system is based on the notion of the “case,” with the case being best thought of as the unit of analysis for the current study. Cases in a project might be individuals, organizations, sites, and/or other

analytic units. The information gathered for a case can come from a single document, such as an interview or response to a survey; from parts of a document, such as for a member of a focus group; or from across several documents, such as repeat interviews in a longitudinal study, or when data about the case are generated using multiple sources or methods. All this information, along with any demographic or numeric data relating to the case, is brought together within a structural unit for each case. This structure then facilitates both within-case and cross-case analyses and is of particular value in projects involving complex data sources (i.e., anything other than single interviews).

Designing With NVivo

There are three ways (at least) in which NVivo can assist in the process of research design, regardless of the methodological approach to be adopted in the research. These are through keeping a research journal, working with literature, and building mind maps and conceptual models.

Keeping a Research Journal

Journaling—even just keeping rough notes—from the very beginning of a project serves to prevent loss of ideas that might be worthy of follow-up, and in the process, to stimulate fresh thinking about the study being planned. Keeping a record of decisions made when planning and conducting a research project also helps, later on, with preparing an accurate record of the methods adopted for the project and the rationale for those methods.

NVivo can import text from Microsoft Word, or a journal can be created and recorded progressively as a file within NVivo. Some researchers keep all their notes in a single document; others make several documents, perhaps to separate methodological from substantive issues. A research journal is a notoriously messy document, comprising random thoughts, notes of conversations, ideas from reading, and perhaps even carefully considered strategies, entered in no particular sequence. Keeping the journal in NVivo means that the researcher can code its content and then, later, immediately retrieve any thoughts or information related to any particular aspect of the project, regardless of how messy the original document was. Seeing all the material on one topic together prompts deeper thinking and perhaps reconceptualization of that topic. Additionally, the content of the journal can be hyperlinked to

external files or web pages, or internally, to content of files within the NVivo project. In later stages of a project, “see-also” links will be used to link a reflection or conclusion to the evidence that prompted it, which becomes of great benefit when writing a report from the data.

Working With Literature

NVivo’s coding system can be used also to code, retrieve, and synthesize what is learned from reading across the substantive, theoretical, or methodological literature during the design phase of a project. Searching text to locate all finds of particular words or phrases provides a useful supplement to coding. Thus, as with the journal, when using coding or searching, the researcher is able to locate and bring together, from across all or selected references, any available material on, for example, the concept of equity, or debates about the use of *p* values, or the role of antioxidants in preventing cancer. See-also links, again, are used to connect specific passages in the literature with reflective ideas, or with other data.

Literature is imported directly as PDF sources, or selected references are imported with associated notes and metadata from a bibliographic database. If these sources were named with the authors and year of publication, then any retrieved segments of coded text will be identified with those, further facilitating the preparation of a written review of the literature. The database created in NVivo becomes available not only for this project but can also serve as an ongoing database for designing, conducting, and writing up future projects.

A preliminary review of the literature can be extended into a more thorough analysis by drawing on NVivo’s tools for recording and using metadata about sources (stored as attributes of the PDF files) in comparative analyses or by examining the relationship between, say, perspectives on one topic and what is said about another. Recorded information about each reference could be used, for example, to review changes over time in perspectives on a particular concept, or perhaps to compare the key concerns of North American versus European writers; associations between codes, or between attributes and codes, could be used to review the relationship between an author’s theoretical perspective and their views on alternative strategies for dealing with a social or environmental problem.

Building Conceptual Models

Researchers often find it useful to map their ideas about their research design or about what they are expecting to find from their data gathering at the start of a project. Doing so can help to identify factors relevant to the topic of the research that might need to be considered, or to think through a process. Additionally, drawing a conceptual map or process model prompts awareness of sampling or validity issues to be considered and solved.

NVivo provides two mapping tools useful at the design stage of a project. Starting with a main idea, a branching mind map records linked items and ideas that come to mind as one thinks further about the topic and its subtopics. This map can be converted into a preliminary ready-made (but modifiable) coding system that can be used to gather journal notes, literature, and data from initial sources for each of the topics or other items.

Alternatively, a conceptual map can be drawn to explore a concept or record a process (e.g., to map a theory of change in an evaluation project), using a variety of shapes with associative, unidirectional, or bidirectional links between them. Labels are added to items in the model; color emphasizes the organization, meaning, or significance of different items. Models can be archived, allowing the researcher to work on a copy and so continue to modify the model as their understanding grows, while keeping a historical record of their developing ideas. As the project develops, project items such as files, cases, or codes can be added to a conceptual map to reflect growing understanding, with direct links to the underlying data.

Designing for Analysis Using NVivo

When the researcher's intention is to use NVivo for analysis of qualitative or mixed methods data, there are a number of points to be aware of at the design stage of the project that will facilitate effective (and efficient) use of NVivo's coding and query tools.

As noted earlier, much of NVivo's data management system is based on the designation and construction of cases, which serve as foci for data collection and as units of analysis. It is useful, therefore, to identify who or what are the cases for a project early in the life of the project, even if the actual structures to hold them are left until sometime later. It is helpful, also, to plan for what kind of demographic, categorical, or scaled data will be needed when analyzing data for each case, to ensure it is collected along with other qualitative data.

Additionally, sources and cases can be organized into one or more sets, and so preliminary thinking at

the design stage is needed about whether contextual data are best recorded as an attribute of a case or using a set. Thus, for example, in a study of children with attention deficit hyperactivity disorder, one might interview the children, their parents, their teachers, and their doctors; observe the families in interaction; and record a number of demographic and scaled measures about each child. All the information relating to each child, regardless of from whom it came, would be referenced in a case for that child, along with all the demographic data and scores, allowing for within-case and cross-case analysis. As well, one could create a set of child interviews, a set of parent interviews, a set of teacher interviews, and so on, allowing for within-set or between-set analyses. Once the content of the various data sources has also been coded for concepts and themes, the enormous flexibility of this data management system, with its codes, cases, attributes of cases, and sets, allows for a very wide range of questions and analysis strategies.

As well as the conceptual work in thinking about cases, attributes, sets, and potential codes one does to design for analysis, there are some very practical matters relevant to data planning and preparation to consider:

1. Most data imported into NVivo are prepared in Word, although it is also possible to import and code video, audio, and image data, PDF documents, survey data, web pages, and Twitter data. Unless transcribed by the interviewer, allow time for careful editing of files before importing them.
2. Develop a clear labeling system for files for convenience when establishing cases and sets. Thus, a document labeled "Josef-mother interview T2" can easily be assigned to a case for Josef, a set for mothers, and a set for Time 2 (use a pseudonym, if necessary, for each case). Thus, all documents relevant to Josef's case ideally include his name in their titles, while his case will simply be named "Josef." His attribute data will also be listed under "Josef," so that it exactly matches his case name and is correctly assigned when imported.
3. When data are embedded within a multi-case source such as a focus group discussion, label contributions to that discussion with the speaker's name. NVivo can then automatically reference those contributions in the appropriate cases, saving a lot of interactive coding time. Plan ahead to have an observer sequentially record who is speaking and the first word they say, to match with the transcript of the discussion so that speakers can be identified, thus avoiding confusion.

With cases, coding, attributes, and sets in place, NVivo's query functions facilitate asking comparative questions of the data and exploring relational patterns in the data that go well beyond simple thematic analysis. Results of these analyses are often usefully presented in a matrix—a kind of “qualitative cross tabulation.” In these, the links between case attributes, sets, and coded text can be explored, or the links between pairs of codes are examined, to answer questions about the pattern of associations between, say, particular demographic or contextual conditions and a range of actions, or between actions and different emotions, with results for each association revealing both how often it occurs and the content of the underlying qualitative data for each connection. All coding information, including results from queries, can be exported in numeric form for further statistical analysis if appropriate—but always with the supporting text readily available in the NVivo database to give substance and meaning to the numbers.

OBSERVATIONAL RESEARCH

The observation of human and animal behavior has been referred to as the sine qua non of science, and indeed, any research concerning behavior ultimately is based on observation. A more specific term, *naturalistic observation*, traditionally has referred to a set of research methods wherein the emphasis is on capturing the dynamic or temporal nature of behavior in the environment where it naturally occurs, rather than in a laboratory where it is experimentally induced or manipulated. What is unique about the more general notion of observational research, however, and what has made it so valuable to science is the fact that the process of direct systematic observation (that is, the *what, when, where, and how* of observation) can be controlled to varying degrees, as necessary, while still permitting behavior to occur naturally and over time. Indeed, the control of what Roger Barker referred to as “the stream of behavior,” in his 1962 book by that title, may range from a simple specification of certain aspects of the context for comparative purposes (e.g., diurnal vs. nocturnal behaviors) to a full experimental design involving the random assignment of participants to strictly specified conditions.

Even the most casual observations have been included among these research methods, but they typically involve, at a minimum, a systematic process of specifying, selecting, and sampling behaviors for observation. The behaviors considered might be maximally inclusive, such as in the case of the *ethogram*, which attempts to provide a comprehensive description of all of the characteristic behavior patterns of a species, or they might be restricted to a much smaller set of behaviors, such as the social behaviors of jackdaws, as studied by the Nobel Prize-winning ethologist Konrad

Lorenz, or the facial expressions of emotion in humans, as studied by the psychologist Paul Ekman. Thus, the versatile set of measurement methods referred to as *observational research* emphasizes temporally dynamic behaviors as they naturally occur, although the conditions of observation and the breadth of behaviors observed will vary with the research question(s) at hand.

Because of the nature of observational research, it is often better suited to hypothesis generation than to hypothesis testing. When hypothesis testing does occur, it is limited to the study of the relationship(s) between/ among behaviors, rather than to the causal links between them, as is the focus of experimental methods with single or limited behavioral observations and fully randomized designs. This entry discusses several aspects of observational research: its origins, the approaches, special considerations, and the future of observational research.

Origins

Historically, observational research has its roots in the naturalistic observational methods of Charles Darwin and other naturalists studying nonhuman animals. The work of these 19th-century scientists spawned the field of ethology, which is defined as the study of the behavior of animals in their natural habitats. Observational methods are the primary research tools of the ethologist. In the study of human behaviors, a comparable approach is that of ethnography, which combines several research techniques (observations, interviews, and archival and/ or physical trace measures) in a long-term investigation of a group or culture. This technique also involves immersion and even participation in the group being studied in a method commonly referred to as participant observation.

The use of observational research methods of various kinds can be found in all of the social sciences—including, but not limited to, anthropology, sociology, psychology, communication, political science, and economics—and in fields that range from business to biology, and from education to entomology. These methods have been applied in innumerable settings, from church services to prisons to psychiatric wards to college classrooms, to name a few.

Distinctions Among Methods

Whether studying humans or other animals, one of the important distinctions among observational research methods is whether the observer's presence is overt or *obtrusive* to the participants or covert or *unobtrusive*. In the former case, researchers must be wary of the problem of *reactivity of measurement*—that is, of measurement procedures where the act of measuring may, in all likelihood, change the behavior being measured. Reactivity can operate in a number of ways. For example, the physical space occupied by an observer under a particular tree or in the corner of a room may militate against the occurrence of the behaviors that would naturally occur in that particular location. More likely, at least in the case of the study of human behavior, participants may attempt to control their behaviors in order to project a certain image. One notable example in this regard has been termed *evaluation apprehension*. Specifically, human participants who know that they are being observed might feel apprehensive about being judged or evaluated and might attempt to behave in ways that they believe put them in the most positive light, as opposed to behaving as they would naturally in the absence of an observer. For example, anthropological linguists have observed the hypercorrection of speech pronunciation “errors” in lower- and working-class women when reading a list of words to an experimenter compared to when speaking casually. Presumably, compared to upper-middle-class speakers, they felt a greater need to “speak properly” when it was obvious that their pronunciation was the focus of attention. Although various techniques exist for limiting the effects of evaluation apprehension, obtrusive observational techniques can never fully guarantee the nonreactivity of their measurements.

In the case of unobtrusive observation, participants in the research are not made aware that they are being observed (at least not at the time of observation). This can effectively eliminate the problem of measurement reactivity, but it presents another issue to consider when the research participants are

humans; namely, the ethics of making such observations. In practice, ethical considerations have resulted in limits to the kinds of behaviors that can be observed unobtrusively, as well as to the techniques (for example, the use of recording devices) that can be employed. If the behavior occurs in a public place where the person being observed cannot reasonably expect complete privacy, the observations may be considered acceptable. Another guideline involves the notion of *minimal risk*. Generally speaking, procedures that involve no greater risk to participants than they might encounter in everyday life are considered acceptable. Before making unobtrusive observations, researchers should take steps to solicit the opinions of colleagues and others who might be familiar with issues of privacy, confidentiality, and minimal risk in the kinds of situations involved in the research. Research conducted at institutions that receive federal funding will have an institutional review board composed of researchers and community members who review research protocols involving human participants and who will assist researchers in determining appropriate ethical procedures in these and other circumstances.

Special Considerations

Observational research approaches generally include many more observations or data points than typical experimental approaches, but they, too, are reductionistic in nature; that is, although relatively more behaviors are observed and assessed, not all behaviors that occur during data collection may be studied. This fact raises some special considerations.

How Will the Behaviors Being Studied Be Segmented?

Aristotle claimed that “natural” categories are those that “carve at the joint.” Some behaviors do seem to segment relatively easily via their observable features, such as speaking turns in conversation, or the beginning and end of an eye blink. For many other behaviors, beginnings and endings may not be so clear. Moreover, research has shown that observers asked to segment behaviors into the smallest units they found to be natural and meaningful formed different impressions than observers asked to segment behaviors into the largest units they found natural and meaningful, despite observing the same videotaped series of behaviors. The small-unit observers also were more confident of their impressions. Consumers of observational research findings should keep in mind that different

strategies for segmenting behavior may result in different kinds of observations and inferences.

How Will Behavior Be Classified or Coded?

The central component of all observational systems is sometimes called a behavior code, which is a detailed description of the behaviors and/or events to be observed and recorded. Often, this code is referred to as a *taxonomy* of behavior. The best taxonomies consist of a set of categories with the features of being *mutually exclusive* (that is, every instance of an observed behavior fits into one and only one category of the taxonomy) and *exhaustive* (that is, every instance of an observed behavior fits into one of the available categories of the taxonomy).

Are the Classifications of Observed Behaviors Reliable Ones?

The coding of behaviors according to the categories of a taxonomy have, as a necessary condition, that the coding judgments are reliable ones. In the case of *intra-rater reliability*, this means that an observer should make the same judgments regarding behavior codes if the behaviors are observed and classified again at another time. In the case of *interrater reliability*, two (or more) judges independently viewing the behaviors should make the same classifications or judgments. Although in practice, reliability estimates seldom involve perfect agreement between judgments made at different times or by different coders, there are standards of disagreement accepted by researchers based upon the computations of certain descriptive and inferential statistics. The appropriate statistic(s) to use to make a determination of reliability depends upon the nature of the codes/variables being used. Correlations often are computed for continuous variables or codes (that is, for classifications that vary along some continuum, for example, degrees of displayed aggression), and Cohen's kappa coefficients often are computed for discrete or categorical variables or codes, for example, types of hand gestures.

What Behaviors Will Be Sampled?

The key to sampling is that there is a sufficient amount and appropriate kind of sampling performed such that one represents the desired population of behaviors (and contexts and types of participants) to which one would want to generalize. Various sampling procedures exist, as do statistics to help one ascertain the number of observations necessary to test the reliability of the measurement scheme employed and/or

test hypotheses about the observations (for example, power analyses and tests of effect size).

Problems Associated With Observational Research

Despite all of the advantages inherent in making observations of ongoing behavior, a number of problems are typical of this type of research. Prominent among them is the fact that the development and implementation of reliable codes can be time-consuming and expensive, often requiring huge data sets to achieve representative samples and the use of recording equipment to facilitate reliable measurement. Special methods may be needed to prevent, or at least test for, what has been called *observer drift*. This term refers to the fact that, with prolonged observations, observers may be more likely to forget coding details, become fatigued, experience decreased motivation and attention, and/or learn confounding habits. Finally, observational methods cannot be applied to hypotheses concerning phenomena not susceptible to direct observation, such as cognitive or affective variables. Indeed, care must be taken by researchers to be sure that actual observations (e.g., he smiled or the corners of his mouth were upturned or the zygomaticus major muscle was contracted) and not inferences (e.g., he was happy) are recorded as data.

Future Outlook

With the increasing availability and sophistication of computer technology, researchers employing observational research methods have been able to search for more complicated patterns of behavior, not just within an individual's behavior over time but among interactants in dyads and groups as well. Whether the topic is family interaction patterns, courtship behaviors in *Drosophila*, or patterns of nonverbal behavior in doctor-patient interactions, a collection of multivariate statistical tools, including factor analyses, time-series analyses, and t-pattern analyses, has become available to the researcher to assist him or her in detecting the hidden yet powerful patterns of behavior that are available for observation.

OBSERVATIONS

Observations refer to watching and recording the occurrence of specific behaviors during an episode of interest. The observational method can be employed in the laboratory as well as a wide variety of other settings to obtain a detailed picture of how behavior unfolds. This entry discusses types of observational design, methods for collecting observations, and potential pitfalls that may be encountered.

Types of Observational Designs

There are two types of observational design: naturalistic and laboratory observations. Naturalistic observations entail watching and recording behaviors in everyday environments such as animal colonies, playgrounds, classrooms, and retail settings. The main advantage of naturalistic observation is that it affords researchers the opportunity to study the behavior of animals and people in their natural settings. Disadvantages associated

with naturalistic observations are lack of control over the setting; thus, confounding factors may come into play. Also, the behavior of interest may be extremely infrequent and unlikely to be captured during observational sessions.

Laboratory observations involve watching and recording behaviors in a laboratory setting. The advantage of laboratory observations is that researchers can structure them to elicit certain behaviors by asking participants to discuss a particular topic or complete a specific task. The major disadvantage is that participants may behave unnaturally because of the contrived nature of the laboratory.

Collecting Observations

Specifying the Behavior of Interest

The first step in collecting observations is to specify the behavior(s) of interest. This often consists of formulating an operational definition, or precisely describing what constitutes an occurrence of each type of behavior. For instance, physical aggression may be operationally defined as hitting, kicking, or biting another person. Thus, when any of these behaviors occur, the researcher would record an instance of physical aggression. Researchers often create coding manuals, which include operational definitions and examples of the behaviors of interest, to use as a reference guide when observing complex behaviors.

Recording Observations

Researchers use different methods for recording observations dependent on the behavior of interest and the setting. One dimension that may differ is whether observations are made live or while watching a recording of the episode. Researchers often choose to record simple behaviors live and in real time as they occur. In situations characterized by complexity, researchers often elect to make a DVD/video recording of the episode. This gives researchers more flexibility in recording a variety of behaviors, most notably the ability to progress at their own speed, or to watch behaviors again if needed.

Similarly, researchers may choose to record behavior by making hand tallies or using computers. If the behavior of interest is simple, researchers may choose to record each time a behavior occurs. Many researchers, however, choose to use a computer to facilitate observational research. Several computer programs are available for recording observations. Computer entry allows for exact timing of behavior so that researchers can determine time lags between particular instances of behavior.

Another choice in recording behavior is whether to use time or event sampling. Time sampling involves dividing the observational time session into short time periods and recording any occurrences of the behavior of interest. For instance, researchers studying classroom participation might divide a 1-hour class into twelve 5-minute intervals. They could then record if students participated in each interval and then determine the percentage of intervals that included student participation. A second option is to use event sampling, recording each behavior of interest as it occurs. Researchers using the event sampling technique in the classroom participation example would record each time a student participated in class and would ultimately calculate the frequency of student participation across the class period.

Ensuring Interrater Reliability

Interrater reliability refers to agreement among observers and is necessary for scientifically sound observations. Several steps can be taken to ensure high interrater reliability. First, new observers often receive detailed training before they begin to code observational data. In many cases, novice observers also practice with DVD/video recordings to gain experience with the observational task. Finally, two or more observers often code a percentage of the episodes to ensure that agreement remains high.

Potential Pitfalls

There are two potential dangers in collecting observations: observer influence and observer bias. Observer influence refers to changes in behavior in response to the presence of an observer. Individuals may be cognizant of the observer and alter their behavior, often in a more positive direction. The term *Hawthorne effect* is often used to refer to these increases in positive (e.g., prosocial, productive) behavior in response to an observer. Steps can be taken in order to reduce observer influence, including utilization of adaptation periods during which observers immerse themselves in the environment prior to data collection so that the subjects of their observation become accustomed to their presence.

Another potential danger is observer bias, in which observers' knowledge of the study hypotheses influences their recording of behavior. Observers may notice and note more behavior that is congruent with the study hypotheses than actually occurs. At the same time, they may not notice and note behavior that is incongruent with the study hypotheses. One means of lessening observer bias is to limit the information given to observers regarding the study hypotheses.

OCCAM'S RAZOR

Occam's razor (also spelled Ockham) is known as the *principle of parsimony* or the *economy of hypotheses*. It is a philosophical principle dictating that, all things being equal, simplicity is preferred over complexity. In philosophy, *razor* refers to a razor blade and suggests that one should cut away unnecessary complications. Traditionally, the razor has been used as a philosophical heuristic for choosing between competing theories, but the principle is also useful for defining methods for empirical inquiry, selecting scientific hypotheses, and refining statistical models. According to Occam's razor, a tool with fewer working parts ought to be selected over one with many, provided they are equally functional. Likewise, a straightforward explanation ought to be believed over one that requires many separate contingencies.

For instance, there are a number of possible reasons why a light bulb does not turn on when a switch is flipped: Aliens could have abducted the light bulb, the power could be out, or the filament within the bulb has burned out. The explanation requiring aliens is exceedingly complex, as it necessitates the existence of an unknown life form, a planet from which they have come, a motive for taking light bulbs, and so on. A power outage is not as complicated but still requires an intricate chain of events, such as a storm, accident, or engineering problem. The simplest of these theories is that the light bulb has simply burned out. All theories provide explanations but vary in complexity. Until proof corroborating one account surfaces, Occam's razor requires that the simplest explanation be preferred above the others. Thus, the logical—and most likely correct—hypothesis is that the light bulb has burned out.

This entry begins with a brief history of Occam's razor. It then discusses the implications for research. The entry concludes with some caveats related to the use of Occam's razor.

History

Occam's razor is named for the 14th-century English theologian, philosopher, and friar William of Occam. William, who was presumably from the city of Occam, famously suggested that "entities should not be multiplied beyond necessity." To do so, he explained, implied vanity and needlessly increased the chances of error. This principle had been formalized since the time of Aristotle, but Occam's unabashed and consistent use of the razor helped Occam become one of the foremost critics of Thomas Aquinas.

Implications for Scientific Research

The reasons for emphasizing simplicity when conceptualizing and conducting research may seem obvious. Simple designs reduce the chance of experimenter error, increase the clarity of the results, obviate needlessly complex statistical analyses, conserve valuable resources, and curtail potential confounds. As such, the razor can be a helpful guide when attempting to produce an optimal research design. Although often implemented intuitively, it may be helpful to review and refine proposed research methods with the razor in mind.

Just as any number of tools can be used to accomplish a particular job, there are many potential methodological designs for each research question. Occam's razor suggests that a tool with fewer working parts is preferable to one that is needlessly complicated. A correlation design that necessitates only examining government records may be more appropriate than an experimental design that necessitates recruiting, assigning, manipulating, and debriefing participants. If both designs would yield the same conclusion, Occam's razor dictates that the simpler correlation design should be used.

Although the razor is implicitly useful in selecting a design, its overt utility can be seen when streamlining research. Before beginning any research endeavor, it is wise to determine the value of each component. Occam's razor reasonably warns against the implementation of any component that needlessly complicates the enterprise. Although the use of new technology, participant deception, or novel methodology may be considered *sexy* or *fun* research, the inclusion of such factors may sacrifice the validity or reliability of the investigation.

The principle of Occam's razor is also apparent in some statistical analyses. A regression analysis is a statistical tool that allows a researcher to assess the contribution

of multiple independent variables on a single dependent variable. After determining the relative contribution of each independent variable, the researcher must adjust his or her model to include only those variables that add enough descriptive information to warrant their inclusion. A regression model with two independent variables should not include a third unless it accounts for additional unique variance. A model with two independent variables, for instance, that account for 80% of the variance of the dependent variable is preferable to a model with three variables that account for the same 80%. Its inclusion precisely mimics the needless multiplication of entities prohibited by Occam. A model with three independent variables is considerably more complex than a model with two independent variables. Because the third variable does not contribute information to the model, Occam's razor can be used to cut it away.

Caveats

In practice, a strict adherence to Occam's razor is usually impossible or ill-advised, as it is rare to find any two models or theories that are equivalent in all ways except complexity. Often, when some portion of a method, hypothesis, or theory is cut away, some explanatory or logical value must be sacrificed. In the previously mentioned case of the regression analysis, the addition of a third independent variable may contribute a small amount of descriptive value, perhaps .01%. It is unlikely that a variable accounting for .01% of the variance will significantly affect a model and deem inclusion. If it accounted for 5%, it would be more tempting to accept a more complicated model by allowing it to remain; and if it accounted for 10%, it would certainly pass the razor without being sliced away.

Furthermore, it should not be assumed that one extremely complicated hypothesis or variable is preferred over two simple ones. For instance, a model using one variable, *weather*, may be just as predictive as a model with two variables, *temperature* and *humidity*. Although it appears that the first model is the simpler—and therefore preferable by Occam's razor—the variable, *weather*, is likely to contain many discrete subvariables such as cloud cover, barometric pressure, and wind as well as temperature and humidity. Although simply stated, *weather* is not a simple concept. It is important to remember that Occam's razor advocates simplicity, which is not to be confused with brevity.

Conclusion

At its best, the razor is used to trim unnecessary complexities from any theory or design, leaving only that which can be directly used to answer the research

question. Correct use of the razor at each step of the research process will reduce any final product to its most efficient, elegant, and consumable form, maximizing accuracy and reducing error.

ODDS

Let the probability of the occurrence of an event be denoted by p , thereby implying that $1 - p$ represents the probability of the nonoccurrence of the event. Succinctly, the *odds* of the occurrence of the event are defined as the ratio of the probability of the occurrence to the probability of the nonoccurrence, or $\frac{p}{1-p}$.

Odds are often encountered in gambling situations. A pertinent example can be extracted from a football game. For instance, if a Vegas odds maker assigns an 80% probability of a football team from western New York winning a game against another team from eastern Massachusetts, the suggested odds of the football team from western New York winning are $\frac{0.8}{1-0.8} = 4.0$.

If the odds can be represented in terms of a fraction $\frac{a}{b}$, where a and b are both integers, the odds are often referred to as “ a -to- b .” Thus, the odds in favor of the team from western New York winning the game would be quoted as “four-to-one.”

In the context of gambling, a “fair game” is one in which both the house and the gambler have an expected gain of zero. Indeed, if the odds maker sets the odds of the team from western New York winning at four-to-one, and the perceived odds among gamblers are consistent with this assignment, then the average gain for both the house and the gamblers should be near zero. In this setting, if a gambler has the discretionary income to bet \$1 in favor of the eastern Massachusetts football team, and the team from eastern Massachusetts wins the game, the gambler would

receive $4 \times \$1 = \4 , in earnings plus all monies with which the bet was made (\$1), thus accumulating a total of \$5. Conversely, should the gambler choose to bet \$1 in favor of the western New York football team, and the team from western New York prevails, the gambler would receive $\frac{1}{4} \times \$1 = \0.25 in earnings plus all monies with which the bet was placed (\$1), thus accumulating a total of \$1.25. Neither the gambler nor the house experiences a positive expected gain because the odds of the team from western New York defeating the team from eastern Massachusetts directly offset the difference in payouts.

In biostatistics, odds are often used to characterize the likelihood of a disease or condition. For example, if 100 people within a small village of 1,100 people contract a certain disease, then the odds of a randomly selected resident contracting the disease are $\frac{100}{1,100} = 0.1$.

An interpretation of this measure would be that the probability of becoming infected with the disease is 0.1 times the probability of not developing the disease.

Care must be taken to distinguish between odds and probability, especially when the measures are both between 0 and 1. Consider, for instance, tossing an unbiased, six-sided die. The probability of rolling a 1 is $\frac{1}{6}$; however, the odds of rolling a 1 are $\frac{1}{5}$, or “one-to-five.”

For any event that is not impossible, the odds are always greater than the probability. The previous examples illustrate this fact. The probability of a western New York football team victory is set at 0.8, whereas the odds are 4.0. The probability of a villager contracting the disease is 0.091, whereas the odds are 0.1. The probability of rolling a 1 in a die toss is 0.167, whereas the odds are 0.2.

Probability is bounded between zero and one. In other words, the probability of the occurrence of an event, p , is such that $0 \leq p \leq 1$. Odds are bounded between zero and infinity, or

$$0 \leq \frac{p}{1-p} < \infty,$$

when $0 \leq p < 1$.

When the probability of the occurrence of an event is small, the odds and the probability are very similar. This is evident in the disease example. The probability of the event (becoming diseased) is small, and so the probability, 0.091, and the odds, 0.1, are quite close.

If p_1 represents the probability of an event occurring and p_2 represents the probability of a second event

occurring, the ratio of the odds of the two events, known as the *odds ratio*, is

$$\frac{p_1}{1-p_1} / \frac{p_2}{1-p_2}.$$

Often, in comparing the odds for two events, the individual odds are not reported, but rather the odds ratio is used. Another common measure based on the odds is the log of the odds,

$$\log\left(\frac{p}{1-p}\right),$$

which is commonly referred to as the logit and plays an integral part in *logistic regression*. The logit is unbounded and may assume any value:

$$-\infty < \log\left(\frac{p}{1-p}\right) < \infty.$$

It thereby provides a more convenient measure to model than the odds or the probability, both of which are bounded.

ODDS RATIO

The odds ratio (OR) is a measure of association that is used to describe the relationship between two or more categorical (usually dichotomous) variables (e.g., in a contingency table) or between continuous variables and a categorical outcome variable (e.g., in logistic regression). The OR describes how much more likely an outcome is to occur in one group as compared to another group. ORs are particularly important in research settings that have dichotomous outcome variables (e.g., in medical research).

As the name implies, the OR is the ratio of two “odds,” which are, in turn, ratios of the chance or probability of two (or more) possible outcomes.

Suppose one were throwing a single die and wanted to calculate the odds of getting a 1, 2, 3, or 4. Because there is a 4 in 6 chance of throwing a 1 through 4 on a single die, the odds are 4/6 (the probability of getting a 1 through 4) divided by 2/6 (2/6 is the probability of not getting a 1 through 4, but rather getting a 5 or 6) or 4/2 = “2 to 1” = 2.

An Example: Odds Ratios for Two Dichotomous Outcomes

David P. Strachan, Barbara K. Butland, and H. Ross Anderson report on the occurrence of hay fever for 11-year-old children with and without eczema and present the results in a contingency table (Table 1).

First, the probability of hay fever for those with eczema (the top row) is calculated. This probability is $141/561 = .251$. Thus, the odds of hay fever for those with eczema are

$$\frac{\frac{141}{561}}{\frac{420}{561}} = \frac{141}{420} = .34,$$

about 1 to 3. Analogously, the probability of hay fever for those without eczema is $\frac{928}{14,453} = .064$, and the odds are $\frac{928}{13,525}$. The OR in this example is defined as

the odds of hay fever for eczema patients divided by the odds of hay fever for noneczema patients. The OR, therefore, is

$$\frac{\frac{141}{420}}{\frac{928}{13,525}} = \frac{141 \times 13,525}{420 \times 928} = 4.89. \quad (1)$$

From the example, one can infer that the odds of hay fever for eczema sufferers are 4.89 times the odds

Table 1 Contingency Table of Observed Numbers of Cases of Eczema and Hay Fever

Eczema	Hay Fever		Total
	Yes	No	
Yes	141	420	561
No	928	13,525	14,453
Total	1,069	13,945	15,014

for noneczema patients. Thus, having eczema almost quintuples the odds of getting hay fever.

The ratio of the two odds can, as shown in Equation (1), also be computed as a ratio of the products of the diagonally opposite cells and is also referred to as the *cross-product ratio*.

The OR is bounded by zero and positive infinity. Values above and below 1 indicate that the occurrence of an event is more likely for one or the other group, respectively. An OR of exactly 1 means that the two odds are exactly equal, implying complete independence between the variables.

Does the Odds Ratio Imply a Significant Relationship?

To determine whether or not this OR is significantly different from 1.0 (implying the observed relationship or effect is most likely not due to chance), one can perform a null hypothesis significance test. Usually, the OR is first transformed into the *log odds ratio* [$\log(\text{OR})$] by taking its natural logarithm. Then, this value is divided by its standard error and the result compared to a test value. In this example, the OR of 4.89 is transformed to the $\log(\text{OR})$ of 1.59. A $\log(\text{OR})$ of 0 implies independence, whereas values further away from 0 signify relationships in which the probability or odds are different for the two groups. Note that $\log(\text{OR})$ is symmetrical and is bounded by negative and positive infinity.

The standard error (SE) of the $\log(\text{OR})$ is defined as

$$SE_{\log(\text{OR})} = \sqrt{\frac{1}{n_{11}} + \frac{1}{n_{12}} + \frac{1}{n_{21}} + \frac{1}{n_{22}}}, \quad (2)$$

where n_{11} to n_{22} are sample sizes of the four cells in the contingency table. Using this formula, the $SE_{\log(\text{OR})}$ in the example is

$$SE_{\log(\text{OR})} = \sqrt{\frac{1}{141} + \frac{1}{420} + \frac{1}{928} + \frac{1}{13,525}} = 0.103.$$

$$\text{Thus, } \frac{\log(\text{OR})}{SE_{\log(\text{OR})}} = \frac{1.59}{.103} = 15.44.$$

In large samples, the sampling distribution of $\log(\text{OR})$ can be assumed to be normal and thus can be compared to the critical values of the normal distribution (that is, with $\alpha = .05$, the values ± 1.96). Because the obtained value far exceeds this critical value, the OR can be said to be significantly different from 1 at the .05 level.

Alternatively, one can use the confidence interval approach. The 95% confidence interval for this example's $\log(\text{OR})$ is $1.59 \pm (0.103)(1.96)$ and thus ranges from 1.386 to 1.790. The result of the previous significance test is reflected here by the fact that the interval does not contain 0. Alternatively, the 95% confidence interval around the OR [rather than the $\log(\text{OR})$] can be found. To do so, one takes the antilog of the confidence limits of the $\log(\text{OR})$ interval, yielding a confidence interval around the OR estimate of 4.89 that ranges from 4.00 to 5.99. Because the OR was shown earlier to be statistically significant, the interval will not contain 1.0. Note that the confidence interval around the $\log(\text{OR})$ is symmetrical, whereas that of the OR is not.

Odds Ratios for Continuous Variables and a Categorical Outcome

When a categorical outcome is to be predicted from several variables, either categorical or continuous, it is common to use logistic regression. The results of a logistic regression are often reported in the form of an OR or $\log(\text{OR})$. The interpretation of these coefficients changes slightly in the presence of continuous variables. For example, Dean G. Kilpatrick and colleagues examined risk factors for substance abuse in adolescents. Among many other findings, they report that age was a significant predictor of whether or not a diagnosis of substance abuse was given or not. The logistic parameter coefficient predicting substance abuse from age is 0.67. The OR can be derived from that by simply raising e to the power of this number. The OR is therefore $e^{0.67} = 1.95$. Thus, each additional year of age yields 1.95 times the odds of being diagnosed with a substance abuse problem. ORs do not increase linearly, but exponentially, meaning that an additional 5 years of age has $e^{(0.67) \cdot 5} = e^{3.35} = 28.5$ times the odds.

OGIVE

Ogives are also known as cumulative frequency polygons because they are drawn on the basis of cumulative frequencies. They graphically show the total in a distribution at any given time. Ogives may also be used to determine where a particular observation stands in relation to all the other observations in the analyzed sample or population. In other words, they are useful in calculating percentiles and percentile ranks, particularly the median, the first and third quartiles, and the interquartile range (IQR). They may also be used for comparing data from two or more different samples or populations. This entry focuses on the process of constructing an ogive for both ungrouped and grouped data and on the usage of ogives to calculate percentiles and percentile ranks.

Ogives With Ungrouped Data

Ungrouped data refer to raw data that have not been classified into categories. For example, the scores

obtained by students on a final exam are considered in Table 1.

A frequency table is needed to construct an ogive from the raw data. The frequency table may include the cumulative frequencies, the relative cumulative frequencies, and/or the percentage cumulative frequencies for the analyzed data. In the case of the scores obtained by students on a final exam, the cumulative frequencies show the number of students who scored up to a particular number of points. The relative/percentage cumulative frequencies show the proportion/percentage of students who scored up to a particular number of points (Table 2).

The cumulative frequency distribution is obtained by adding the frequency corresponding to each score (column 2 in Table 2) to the sum of the frequencies of all smaller scores (column 3 in Table 2). For example, the cumulative frequency for the score of 61 is $0 + 2 = 2$, because this is the lowest score obtained by students. The cumulative frequency for the next score (65) is $2 + 2 = 4$. The next cumulative frequency (corresponding to a score of 75) is $4 + 1 = 5$, and so on. This means that, for example, 5 students scored 75 points or less on the final exam, whereas 18 students scored 95 points or less.

Table 1 Ascending Array of the Scores Obtained by Students on a Final Exam

61	61	65	65	75	78	78	84	84	85
85	89	89	89	91	95	95	95	98	98

Table 2 Frequency Table of the Scores Obtained by Students on a Final Exam

Score (1)	Frequency (2)	Cumulative Frequency (3)	Relative Cumulative Frequency (4)	Percentage Cumulative Frequency (5)
61	2	2	0.10	10%
65	2	4	0.20	20%
75	1	5	0.25	25%
78	2	7	0.35	35%
84	2	9	0.45	45%
85	2	11	0.55	55%
89	3	14	0.70	70%
91	1	15	0.75	75%
95	3	18	0.90	90%
98	2	20	1.00	100%
Total	20			

The relative cumulative frequencies are obtained by dividing each cumulative frequency by the total number of observations (20 in this example). The percentage cumulative frequencies are obtained by multiplying the relative cumulative frequency by 100. In relative cumulative frequency terms, it can be concluded from Table 2 that, for example, a proportion of 0.20 of students scored 65 points or less on the final exam. Expressed in percentage, 20% of the students scored 65 points or less.

The cumulative frequency of the highest score always equals the total number of observations (the sum of all frequencies, 20 in this example). The corresponding relative cumulative frequency is always 1.00; the corresponding percentage cumulative frequency is always 100%.

An ogive for the data in Table 2 is drawn using the scores obtained by students on the exam on the x -axis and either the cumulative, the relative, or the percentage cumulative frequencies on the y -axis (Figure 1).

The ogive is read in the same manner as the cumulative frequencies in Table 2. Reading from left to right, the ogive always remains level or increases and can never drop down toward the x -axis. This is because cumulative frequencies are obtained by successive additions, so that the cumulative frequency for a score can be at most equal to, but never less than, the cumulative frequency for the preceding score. A steeper slope on a certain segment of the ogive indicates a greater increase than a more gradual slope. By the time the highest score obtained on the exam is reached, the ogive reaches 100% on the y -axis.

Ogives With Grouped Data

Grouped data refer to data that have been classified into categories. It is important to know how to use

grouped data in order to draw ogives, because larger samples are often presented for simplicity in grouped form. The scores obtained by students on a final exam may be grouped as in Table 3.

An approach similar to the one described in the case of ungrouped data is used to obtain the cumulative frequencies. The cumulative frequency distribution is obtained by adding the frequency corresponding to each group to the sum of the frequencies of all lower range groups. For example, the cumulative frequency for the group 61–70 is $0 + 4 = 4$, because this is the group with the lowest scores obtained by students. The cumulative frequency for the next group (71–80) is $4 + 3 = 7$. The next cumulative frequency (corresponding to the group 81–90) is $7 + 7 = 14$, and so on. This means that, for example, 14 students scored 90 points or less on the final exam.

The relative cumulative frequencies are obtained by dividing each cumulative frequency by the total number of observations (the sum of all frequencies). The percentage cumulative frequencies are obtained by multiplying the relative cumulative frequency by 100. In relative cumulative frequency terms, it can be concluded from Table 3 that, for example, a proportion of 0.20 of students scored 70 points or less on the final exam. In percentage terms, 20% of the students scored 70 points or less.

Similarly to the ungrouped data case, the cumulative frequency of the highest score always equals the total number of observations (20 in this example). The corresponding relative cumulative frequency is always 1.00, and the corresponding percentage cumulative frequency is always 100%.

The ogive for this set of data (Figure 2) is based on any of the cumulative frequencies calculated in Table 3.

Figure 1 Ogive of the Scores Obtained by Students on a Final Exam, Using Ungrouped Data

Figure 2 Ogive of the Scores Obtained by Students on a Final Exam, Using Grouped Data

Table 3 Grouped Frequencies Table for the Scores Obtained by Students on a Final Exam

Score Groups	Frequency	Cumulative Frequency	Relative Cumulative Frequency	Percentage Cumulative Frequency
60	0	0	0.00	0%
61-70	4	4	0.20	20%
71-80	3	7	0.35	35%
81-90	7	14	0.70	70%
91-100	6	20	1.00	100%
Total	20			

Using Ogives to Obtain Percentiles

Percentiles are a measure of position. The k th percentile of a distribution, P_k , is a value such that k percent of the observations are less than or equal to P_k , and $(100 - k)$ percent are greater than or equal to P_k . For example, the 70th percentile of the distribution of grades obtained by students at a final exam is a value such that 70% of the scores fall at or below it. The median (or the second quartile) is the 50th percentile, the value where 50% of the observations fall at or below it, and the other 50% fall at or above it. The other two commonly used percentiles are the first quartile and the third quartile. The first (or lower) quartile, Q_1 , is the 25th percentile; the third (or upper) quartile, Q_3 , is the 75th percentile.

The term often associated with percentiles in the literature is the *percentile rank*. Whereas the percentile refers to the value corresponding to a particular observation, the percentile rank refers to the percentage of observations at or below that value. Thus, if the 70th percentile of the distribution of grades obtained by students at a final exam is 89 points, then 70% of the

scores fall at or below 89 points; the percentile is 89 points, whereas the percentile rank is 70%.

Percentile ranks provide the place of a particular score relative to all other scores above and below it. Thus, they show how a particular score compares to the specific group of scores in which it appears. For example, knowing that a student obtained 78 points on an exam, the percentile rank shows how well the student did compared to the other students in his or her class. If the students obtained very good scores overall, a score of 78 may represent poor performance and thus correspond to a lower percentile. If the test was difficult and the scores were low overall, a score of 78 may actually be among the highest and thus correspond to a higher percentile. Percentiles and percentile ranks may also be used to compare a sample to another sample. Many times, one of the two samples compared is a normative (standard or control) sample.

One way to calculate percentiles and percentile ranks, and to compare samples, is by using the ogive corresponding to the analyzed set of data. However, the

Figure 3 Using the Ogive of the Scores Obtained by Students on a Final Exam to Calculate Percentiles

ogive must be drawn with very high precision for the results to be accurate. It is generally recommended that percentiles and/or percentile ranks be calculated using other methods (i.e., mathematical formulas), because the graphical approach may yield biased results, especially when a very precise representation of the corresponding ogive on grid paper is not available.

To obtain the 70th percentile, the point corresponding to 70% on the y-axis is first marked. A line is then drawn parallel to the x-axis until it intersects the ogive. From that point, a line is drawn parallel to the y-axis until it intersects the x-axis. This intersection point with the x-axis indicates the score corresponding to the 70th percentile: 89. Similarly, the score corresponding to the median (the 50th percentile) is 85 and the score corresponding to the upper quartile (Q3) is 90.

The percentile rank corresponding to a certain score may be obtained by reversing this process. For example, to obtain the percentile rank corresponding to 78 points, the position corresponding to 78 points on the x-axis is marked first; a vertical line is then drawn parallel to the y-axis until it reaches the ogive, and, from the intersection point, a horizontal line is drawn parallel to the x-axis until it reaches the y-axis. This intersection point with the y-axis indicates the percentile rank corresponding to a score of 78 points: 35%. This means that 35% of the students scored 78 points or less on the final exam.

The ogive may also be used to calculate the interquartile range. The interquartile range is a measure of spread showing the distance between the lower and the upper quartiles; it is often used to identify outliers. For the distribution graphed by the ogive in Figure 3, the lower and the upper quartiles may be calculated by employing the method described above. The values of the lower and upper quartiles are 75 and 90, respectively; consequently, the interquartile range is $90 - 75 = 15$.

The ogive may also be useful when comparing data from two or more samples or populations. For example, plotting the ogives for the scores obtained by two

different groups of students on an exam may indicate which batch may have scored better. If the 25th percentile corresponding to Batch A is 78 and the 25th percentile corresponding to Batch B is 55, the conclusion that Batch A scored better on the respective test may be drawn.

OMEGA SQUARED

Omega squared (ω^2) is a descriptive statistic used to quantify the strength of the relationship between a qualitative explanatory (independent or grouping)

variable and a quantitative response (dependent or outcome) variable. The relationship is interpreted in terms of the proportion of variation in the response variable that is associated with the explanatory variable. As a proportion, it can have values between 0 and 1, with 0 indicating no relationship and 1 indicating that all of the variation in the response variable is attributed to the explanatory variable. Omega squared is used as an effect-size index to judge the meaningfulness of the observed relationship identified using the analysis of variance F test. It can supplement the results of hypothesis tests comparing two or more population means. The research design may be either experimental, involving the random assignment of units to levels of the explanatory variable (e.g., different drug treatments), or nonexperimental, involving a comparison of several groups representing existing populations (e.g., underweight, normal weight, overweight, obese).

A Data Example

Consider an experimental study designed to evaluate the merits of three drug treatments to reduce the number of cigarettes smoked (i.e., reduce smoking behavior). From a volunteer group of 150 moderate to heavy smokers, 50 individuals are randomly assigned to each of the three identified drug treatments ($n = 50$). After a 6-week treatment period, participants are asked to record the number of cigarettes smoked during Week 7. Hypothetical means and standard deviations are reported in Table 1.

To test the hypothesis that there is no difference in the average number of cigarettes smoked by individuals exposed to the three drug treatments (i.e., $H_0: \mu_1 = \mu_2 = \mu_3$), the analysis of variance (ANOVA) F test could be used. The sample means estimate the population means, but they are subject to sampling error. The statistical test provides information on whether the observed difference among sample means provides sufficient evidence to conclude that population means differ, or whether it is just a reflection of sampling error. More importantly, the ANOVA F test does not provide any indication of the amount of difference or the strength of the relationship between the treatments and smoking behavior. The statistical test provides only the probability of the observed F statistic if the null hypothesis (i.e., the drugs are equally effective) is true. Differences among population means may be very small, even trivial, and these differences can be detected by the statistical test if the number of individuals in the samples is sufficiently large. Statistical significance does not imply meaningful significance. For the data in Table 1, the results might be judged to be statistically

Table 1 Mean Number of Cigarettes Smoked and Standard Deviations for Each of Three Drug Treatments

<i>Treatment</i>	<i>Mean</i>	<i>Standard Deviation</i>
Drug 1	15	9.8
Drug 2	18	10.7
Drug 3	12	9.2

significant [$F(2,147) = 4.573, p = .011$], and it might be concluded that the drug treatments are differentially effective with respect to smoking behavior. Or, it might be concluded that a relationship does exist between the drug treatments and smoking behavior.

Effect Size

Omega squared provides a measure of association between the grouping factor (e.g., drug type) and the outcome variable (e.g., number of cigarettes smoked). That is, it estimates the proportion of variation in the outcome variable that is associated with the grouping variable. Theoretically, the variance of the population means, σ_G^2 , plus the variance of individual scores within a population, σ_{IG}^2 (which is assumed to be equal for all populations), determines the total variance in the response variable, σ_Y^2 , (i.e., $\sigma_Y^2 = \sigma_G^2 + \sigma_{IG}^2$). In a balanced design (equal number of units per group), ω^2 is

$$\omega^2 = \frac{\sigma_G^2}{\sigma_Y^2} = \frac{\sigma_G^2}{\sigma_G^2 + \sigma_{IG}^2}.$$

To estimate ω^2 ,

$$\hat{\omega}^2 = \frac{SS_{\text{between}} - (J - 1)MS_{\text{within}}}{SS_{\text{total}} + MS_{\text{within}}},$$

where SS_{between} is the between levels of the grouping variable sum of squares, J is the number of groups, SS_{total} is the total sum of squares, and MS_{within} is the within-groups mean square and computed as the sum of squares within groups divided by the degrees of freedom within groups [$MS_{\text{within}} = \frac{SS_{\text{within}}}{(N - J)}$]. For the data in

Table 1, $SS_{\text{between}} = 900$, $J = 3$, $SS_{\text{within}} = 14,463.33$, $MS_{\text{within}} = 98.39$, $SS_{\text{total}} = 15,363.33$, and $\hat{\omega}^2$ equals

$$\hat{\omega}^2 = \frac{900 - (3 - 1)98.39}{15,363.33 + 98.39} = .045.$$

These results can be interpreted as 4.5% of the variation in the number of cigarettes smoked is explained by

the drug treatments. Whereas the maximum value possible for $\hat{\omega}^2$ is 1, actual results from empirical studies are much smaller. One difficulty with $\hat{\omega}^2$ is evaluating its magnitude. Many researchers adopt guidelines for interpreting omega squared suggested by Jacob Cohen to define small, medium, and large relationships as .01, .06, and .14, respectively. These guidelines were originally based on research findings reviewed by Cohen in the 1960s and 1970s. They were not intended to be standards for all response variables, with all populations, in all contexts. However, these guidelines have become standards for many researchers. The interpretation of omega squared should be based on literature reviews and findings reported by other researchers conducting similar inquiries with similar populations but using different response measures.

Factorial Designs

Many research studies include more than a single explanatory variable. These additional explanatory variables may be manipulated variables, or they may be some characteristic of the participants. An example of a second manipulated variable for the study described above might be the time of day when the drugs are administered. Regardless of which drug is taken, it might be of interest to determine whether the time of day when a drug is administered has an effect on the number of cigarettes smoked. That is, a drug may be more effective if taken in the morning rather than at night. An example of a participant characteristic that might be included in the drug study is previous smoking behavior. That is, regardless of which drug is taken, can smoking behavior be affected more among moderate smokers than heavy smokers? The nature of the second factor in the study has an important influence in how omega squared is computed and interpreted. Table 2 presents hypothetical group means for a 2×3 factorial design. These data will be used to discuss how the computation and interpretation of $\hat{\omega}^2$ changes. We will assume the total sample size remains the same with

25 participants available for each Factor 2 by Drug combination ($n = 25$).

Partial Omega Squared

If Factor 2 is a manipulated factor (e.g., time of day), the addition of this factor to a study comparing drug treatments will increase the total variance in the data set. Consequently, the total sum of squares will increase but neither SS_{between} nor MS_{within} will be affected. [Note that for the new data set, there is no interaction ($SS_{\text{interaction}} = 0$) between Factor 2 and drug treatment.] The mean number of cigarettes smoked under each drug type remains the same, and adding a manipulated factor does not change the estimate of variance of individuals within treatment combinations. With the data in Table 2, $SS_{\text{total}} = 19,113.33$ and the sum of squares associated with Factor 2 is 3,750. Omega squared computed with Factor 2 in the design gives the following results:

$$\hat{\omega}^2 = \frac{900 - (3-1)98.39}{19,113.33 + 98.39} = .037.$$

Although the drug treatment means are identical in Tables 1 and 2, the estimate of the strength of the relationship between drug treatment and smoking behavior is reduced 17.7% to .037 because of the addition of Factor 2. What is needed is a statistic that is not influenced by the presence of other manipulated factors in the study.

Partial omega squared (ω_p^2) estimates the relationship between a factor (a manipulated factor or interaction) and the response variable, ignoring all other manipulated factors and interactions. For a balanced factorial design, partial omega squared is defined as

$$\hat{\omega}_p = \frac{\sigma_{\text{factor}}^2}{\sigma_{\text{factor}}^2 + \sigma_{\text{error}}^2},$$

where σ_{factor}^2 is the variance due to the factor of interest, which may be a main effect or an interaction, and

Table 2 Hypothetical Group Means for a 2×3 Factorial Design Studying Drug Effectiveness

	Drug 1	Drug 2	Drug 3	Row Means
Factor 2	b_1	10	13	7
	b_2	20	23	17
	Column means	15	18	12

σ_{error}^2 is the error variance for that effect (e.g., MS_{within}). Partial omega squared is estimated as

$$\hat{\omega}_p = \frac{SS_{\text{factor}} - df_{\text{factor}} MS_{\text{error}}}{SS_{\text{factor}} + (N - df_{\text{factor}}) MS_{\text{error}}},$$

where, in a completely randomized factorial design, $SS_{\text{factor}} = SS_{\text{between}}$ and $MS_{\text{error}} = MS_{\text{within}}$. Using the data in Table 2, partial omega squared is computed as

$$\hat{\omega}_p^2 = \frac{900 - (3 - 1)98.39}{900 + (150 - 2)98.39} = .045.$$

Partial omega squared thus provides the same estimate of the relationship between drug treatments and the number of cigarettes smoked when time of day is included as a factor in the design and when drug treatments is the only factor in the study.

When the second factor in the study is a characteristic (C) of the participants (e.g., moderate or heavy smoker), the use of partial omega squared will result in the estimation of the relationship between the manipulated factor (e.g., drug treatments) and the response variable that is much larger than the estimate obtained when the characteristic is not included. A factor that is a characteristic of the participants does not increase the total variation in the response variable like a manipulated variable does. Rather, the variation associated with the characteristic is part of the within-group variance. That is, $\sigma_{\text{within}}^2 = \sigma_C^2 + \sigma_{I|G}^2$. Keeping the total sum of squares the same for Tables 1 and 2 (i.e., $SS_{\text{total}} = 15363.33$), the MS_{within}^* for the data in Table 2 would equal

$$74.398 \left[\frac{SS_{\text{within}} - SS_C}{N - JK} = \frac{14,463.33 - 3750}{150 - (2)(3)} \right].$$

Using the formula for partial omega squared, the relationship between drug treatments and smoking behavior would equal

$$\hat{\omega}_p^2 = \frac{900 - (3 - 1)74.398}{900 + (150 - 2)74.398} = .063.$$

When the second factor is a characteristic of the participants, the within-group variance is reduced and partial omega squared provides an estimate of the relationship between the first manipulated factor and the response variable that is much greater than an estimate of the relationship when the characteristic is not included in the analysis. In the present example, partial omega squared is 40% greater than when previous smoking behavior is not considered.

To obtain consistent estimates of the relationship between an explanatory and a response variable across a variety of research designs, serious consideration must be given to the design features of the studies. For a between-group design where all of the factors being studied are manipulated, partial omega squared is appropriate, but in the case of one manipulated factor and one factor being a characteristic of the participants, omega squared should be computed for the manipulated factor.

Limitations

In addition to the difficulty of judging the magnitude of $\hat{\omega}^2$ in terms of the meaningfulness of the observed relationship, this effect-size index has several limitations that must be taken into consideration when interpreting its value. Another limitation is the instability of the statistic. A confidence interval (CI) for the parameter can be very wide. For example, using the data in Table 1, $\hat{\omega}^2 = .045$ and the .95CI is (.003, .137). Using Cohen's guidelines to interpret $\hat{\omega}^2$, the current estimate of the relationship between smoking behavior and the drug treatments would be judged to be from virtually nonexistent to large. Given that the present estimate was obtained on a sample size that is much larger than is often found in experimental research, it should be clear from this example that researchers must be careful not to overinterpret the magnitude of the point estimate for $\hat{\omega}^2$.

A second limitation associated with the interpretation of $\hat{\omega}^2$ is its dependence on the levels and strength of the treatment variable. In the present example, three drugs are evaluated; if a control (placebo) condition had been included, or if greater differences in drug doses were included, it is likely that the numerical value for $\hat{\omega}^2$ would increase. The specific levels of the explanatory variable chosen for the study (e.g., types of drugs) influence the magnitude of omega squared.

Another limitation with the numerical value of $\hat{\omega}^2$ is that it is affected by the reliability of both the treatments and the outcome measure. Inconsistency with the implementation of the treatments or how the outcome variable is measured will reduce the numerical value of $\hat{\omega}^2$. Furthermore, the heterogeneity of the population studied affects $\hat{\omega}^2$. The greater the variability among the units being studied, the lower the numerical value for omega squared. In addition, omega squared was developed for a fixed-effect analysis of variance (ANOVA) model. ANOVA assumes that the populations being compared have variances that are identical. Omega squared makes the same assumption. If sample sizes are unequal, violating this assumption is much more serious.

Finally, the research design used in the inquiry can affect the numerical value of $\hat{\omega}^2$. The use of covariates, blocking variables, or repeated measures can make estimates of $\hat{\omega}^2$ incompatible with estimates of omega squared from completely randomized studies. Repeated measures, blocking variables, and covariates reduce error variance, resulting in greater statistical power for hypothesis tests for comparing population means and greater values for omega squared. But the populations being compared are not the same as those compared in a completely randomized study, and so values of omega squared are not comparable.

Conclusion

Omega squared can be a useful descriptive statistic to quantify the strength of the relationship between a qualitative explanatory variable and a quantitative response variable. It has the desirable feature of being a proportion and therefore has values between 0 and 1. Because statistical significance is influenced by the number of units in the study, virtually any relationship can be judged to be statistically significant if the sample size is large enough. Omega squared is independent of sample size, so it provides an index to judge the practicality or meaningfulness of an observed relationship.

Omega squared does have several limitations that should be considered when interpreting its value. First, there is no universally agreed-upon criterion for judging the importance of the estimated strength of relationship. Second, omega squared is an unstable statistic having a wide confidence interval. Third, the reliability of the response and explanatory variables influences the magnitude of the estimated relationship. Fourth, the choice of levels of the explanatory variable affects omega squared. Fifth, the variability and equality of the populations studied can influence its value. And sixth, design features can affect the numerical value of the estimated relationship.

In spite of these limitations, omega squared can provide useful information to aid the interpretation of study results and should be reported along with the results of statistical hypothesis tests.

OMNIBUS TESTS

Omnibus tests are statistical tests that are designed to detect any of a broad range of departures from a specific null hypothesis. For example, one might want to test that a random sample came from a population distributed as normal with unspecified mean and variance. A successful *genuine* omnibus test would lead one to reject this hypothesis if the data came from any other distribution. By contrast, a test of normality that was sensitive specifically to thick-tailed distributions such as Cauchy would not be considered an omnibus test. A genuine omnibus test is consistent for *any* departure from the null, rejecting a false null hypothesis with probability approaching unity as the sample size increases; however, some statisticians include in the omnibus category certain broad-spectrum tests that do not meet this stringent condition. This entry presents general types, general features, and examples of omnibus tests.

Categories

Here are some general types of omnibus tests: (a) tests for differences in means of groups of data distinguished by “treatments,” such as in one-way analysis of variance (ANOVA); (b) tests that combine the results of independent tests of various hypotheses to indicate whether one or more of them is false; (c) tests for time-series models, such as portmanteau tests for adequacy of autoregressive-integrated-moving-average (ARIMA) models and tests for structural breaks; (d) goodness-of-fit tests for hypotheses about marginal or joint distributions, such as tests for univariate or multivariate normality.

General Features

All of these procedures have the advantage of detecting whether *all* aspects of the data are consistent with the hypothesis in question, but this breadth of scope comes at a price: (a) omnibus tests typically do not pinpoint the specific features of the data that are most at variance with the null; and (b) omnibus tests typically have less power against specific departures from the null hypothesis than do tests with narrower focus. Because of these considerations, conducting an omnibus test is most often just a *first* step in statistical analysis. It can help in deciding whether further study is appropriate; for example, if an ANOVA test rejects that all treatment means are equal, one might then seek to identify and explain specific sources of difference. An omnibus test can also help in selecting the best *methods* for further analysis; for example, if the data are consistent with the normality hypothesis, then one has available the usual minimum-variance estimators and uniformly most powerful tests for mean and variance. However, in applying a sequence of tests to *given* data, there is the danger of data snooping (performing repeated analytical tests on a data set in the hope of finding a significant test). Thus, when applied *unconditionally*, a valid .05-level test that two specific treatment means differ would reject a true “no-difference” null in 5% of repeated samples; yet the same test would reject more often if applied to the two of $m > 2$ treatments with the most divergent means in samples for which ANOVA rejects the full m -variate null.

Examples

One-Way ANOVA

Given independent samples (vectors) $Y_1, \dots, Y_m$ of sizes $n_1, \dots, n_m$ we test H_0 that all m population means are equal, assuming that the populations are normal with the same variance. H_0 is rejected at level α if $\sum_j n_j (M_j - M_N)^2 / [(m-1)S_p^2]$ exceeds the upper- α quantile of the F distribution with $m-1$ and $N = \sum_j n_j$ degrees of freedom, where M_j is the mean of sample j , M_N is the overall mean, and S_p^2 is the weighted average of sample variances.

Fisher's Test

Given probability values (p values) $P_1, \dots, P_m$ from *independent* tests of m null hypotheses, the test rejects at level α that *all* are true if $-2[\ln(P_1) + \dots + \ln(P_m)]$ exceeds $\chi^2(m)$, the upper- α quantile of $\chi^2(m)$. The idea is that the combined results might signal statistical significance, although no individual test does so.

Time Series Tests

Time series $Y_1, \dots, Y_{T+d}$ is modeled as an ARIMA(p, d, q) process, and residuals are calculated as $u_t = Z_t - \phi_1 Z_{t-1} - \dots - \phi_p Z_{t-p} + \theta_1 u_{t-1} + \dots + \theta_q u_{t-q}$, where $Z_t = \Delta^d Y_t$ is the d th-order difference. With $r_1, \dots, r_m$ as the residuals' autocorrelations at lags 1, 2, ..., m Y_m the Box–Pierce portmanteau test of the model's adequacy rejects at level α if $T \sum r_j^2 \geq \chi^2_\alpha(m)$. If residuals $\{e_t\}$ from structural model $Y_t = X_t \alpha + \varepsilon_t$ are calculated *recursively* using at each t only prior data, then a structural break—a change in one or more coefficients at any t —can be detected with a cumulative sum test involving sums of squares of the $\{e_t\}$.

Tests of Fit

The many omnibus tests for whether data conform to some particular family of distributions include those based on (a) relative frequencies, such as Pearson's chi-square; (b) moments, such as skewness and kurtosis tests; (c) order statistics; (d) empirical distribution functions; and (e) generating functions. Only tests in Groups (c)–(e) can count as *genuine* omnibus tests, as defined in the opening paragraph. In Group (c), the best known are the Shapiro–Wilk and Shapiro–Francia tests for normality. These compare estimates of standard deviation based on order statistics (the observations in rank order) and on sample moments. In Group (d) are the Kolmogorov–Smirnov (KS) and Anderson–Darling (AD) tests. KS is based on the maximum difference between the cumulative distribution functions of sample and model, $\sup |F_n(x) - F_0(x)|$. AD is based on an integral of squared differences, $\int [F_n(x) - F_0(x)]^2 W(x) dx$, where W is a weight function. This has a simple computational form in terms of order statistics and is typically far more powerful than KS. Group (e) includes tests that compare model and sample moment-generating functions, probability-generating functions, and characteristic functions (c.f.s). With $\phi_0(t) = E(e^{itX} | H_0)$ and $\phi_n(t) = n^{-1} \sum_j \exp(itX_j)$ as the respective c.f.s, tests based on $\int [\phi_n(t) - \phi_0(t)]^2 W(t) \cdot dt$ with appropriate W are *genuine* omnibus tests for any distributional hypothesis.

“ON THE THEORY OF SCALES OF MEASUREMENT”

The 1946 article by Stanley Smith Stevens titled “On the Theory of Scales of Measurement” defined measurement as the assignment of numerals to objects or events according to rules. Stevens went on to discuss how different rules for assigning such numbers resulted in different types of scales. In the remainder of the article, Stevens elaborated on four such scales in terms of the mathematical transformations that can be conducted without changing their properties and the statistical operations that he considered permissible for each. Stevens’s definition of measurement and the four levels of measurement he described have since become iconic in social science measurement.

The four scales of measurement specified by Stevens were the nominal, ordinal, interval, and ratio scales. The scales form a specific hierarchy from low (nominal) to high (ratio) that is ordered on the basis of the types of operations that must be supported in order for a measurement to achieve a particular level. For example, nominal scales must provide for a means of determining distinctiveness, whereas ordinal scales must support the determination of order. The operations are cumulative in the sense that a scale at a higher level supports all of the operations of the scales beneath it, while adding an additional operation. Because of the hierarchical nature of the four measurement scales, they are often referred to as the *levels of measurement*.

Nominal Scales

The nominal scale is at the lowest level of Stevens’s hierarchy. Scales at this level assign numbers only as labels that can be used to distinguish whether attributes of different objects are the same. For example, the numbers “1” and “2” might be assigned to males and females as a shorthand means of differentiating the two. Here, the numbers used are not meaningful in any numerical sense but are simply chosen for convenience. Other numbers, such as 100 and 200, would serve equally well. Permissible transformations of numbers

on a nominal scale include any one-to-one substitution. As an example, assigning the numbers 3 and 4 instead of 1 and 2 would not alter our ability to distinguish between males and females, as long as we knew the “rule” governing this assignment. Because the numbers assigned have no numerical meaning, the only statistics considered to be permissible are those based on counts of the number in each category. Thus, we could determine how many males and females there were, or whether males or females were more numerous. However, we have no way of determining whether one gender is larger or greater than another because numbers in the nominal scale are arbitrary and do not support such a numerical meaning.

Ordinal Scales

In addition to the property of distinctiveness, ordinal scales must have the property of order, or of determining whether one object has more or less of an attribute than another. Thus, ordinal scales provide a means for ordering objects along a continuum of some sort. One familiar example is the outcome of a race. Contestants are ranked according to their order in crossing the finish line, with the first finisher regarded as faster than the second, and so on. Note that such ranks do not provide any information regarding the magnitude of difference between those with different ranks. In other words, based on an ordinal scaling, we have no way of knowing how *much* faster the first-place winner was than the second. Any transformation that preserves the original order is permissible for ordinal scales. For example, a constant such as two could be added to each rank, or different constants could be added to different ranks, as long as doing so did not change the original ordering. Statistical operations considered permissible for ordinal data include computation of the median, percentiles (although see Stevens, 1946, p. 679), and semi-interquartile range. Computations of statistics such as the mean or standard deviation are not considered permissible because they treat the intervals between scale points as equally spaced, which is not a property of ordinal scales.

Likert-type scales that use a response format such as *disagree* to *agree* are, strictly speaking, at the ordinal level of measurement because it is not clear that the intervals are equal. Therefore, statistics such as the mean and standard deviation, and statistical tests such as the *t* test and *F* test, are not considered appropriate. However, methodologists disagree about this, and many feel that the use of such statistics is not problematic provided that the scale has at least five response options that are approximately normally distributed.

Interval Scales

The interval scale adds the requirement that the intervals between adjacent scale points must be equal. A common example is temperature as measured by the Fahrenheit or Centigrade scales, in which the difference between 50° and 51° is considered to be the same as the difference between 90° and 91°. Linear transformations of the form “ $y = a + b * x$ ” are allowable for interval scales because they preserve the equal interval property. Nearly all of the parametric statistical operations, such as calculation of the mean, standard deviation, and product-moment correlation, and statistical tests such as the t test and F test, are considered permissible for intervally scaled data.

Ratio Scales

Ratio scales add the property of an absolute zero point. By “absolute zero,” Stevens meant a point indicating an absolute lack of the property being measured. For example, on a monetary scale, zero means the absolute lack of any money. Ratio scales are more commonly found in the physical than the social sciences because the definition of an absolute zero point is often problematic, and some argue unnecessary, in the latter. Ratio scales support all types of statistical operations. Numbers on a ratio scale can be legitimately transformed only through multiplication of each value on the scale by a constant. Adding a constant to each scale value is not permissible because this would change the value of the zero point, rendering it nonabsolute.

ONE-MODE DATA

Social network analysis deals with the analysis of sets of nodes (actors, individuals, vectors) and ties (edges, arcs, relationship) that make up (social) systems. In this context, a mode describes such a set of node data. One-mode data describe a network in which only one type

of relationship is represented. Multiple modes can exist in one social network data set, but most of the social network research uses one-mode data or converts multiple-mode data into one-mode data for analysis. Both are discussed in this entry.

Definition

A mode can be defined as a type of node that is being studied. Hence, one-mode data describe data that include only one type of node. For instance, this could be a data set that includes data about students in a university. Each and every node represented in that network is of the type student; no other type (mode) exists. Social networks may also include more modes simultaneously, for example, two-mode data. With a two-mode data set, a researcher may not only analyze students but investigate which classes are attended by students. In this network, two modes—students and classes—are present. With one-mode data, a data set represented as a matrix will have the same entities in the rows as in the columns.

Importantly, the discussion of modes is independent of the availability of multiple types of ties in a network (which is another important thread in the social network literature). For example, one may study cognitive and emotional ties among students. This still entails just one mode (students).

Conversion of Multimode Data into One-Mode Data

One-mode data are an important concept even if a researcher works with raw data that have multiple modes, because the options for analysis based on multiple-mode data are still limited (at least as compared to the alternatives available while working with one-mode data). One solution to that problem often chosen by researchers is to convert multimode data into one-mode data before analysis. For example, a two-mode data set, in which persons A and B both attend one event, could be converted into a one-mode data set that includes only nodes A and B and no events as well as a direct tie between A and B (as they have both attended the same event). Once this transformation has been carried out, all the analysis methods available to one-mode social network analysis can be applied. However, the research needs to bear in mind that information was lost in this process of conversion.

ONE-TAILED TEST

One-tailed test is a method of hypothesis testing where the alternative hypothesis specifies in which direction the parameter differs from the value stated in the null hypothesis. That is, the alternative hypothesis states if the parameter is above or below the value in the null hypothesis. One-tailed hypothesis testing is widely used in quantitative research when the direction of the population parameter's deviation from the value in the null hypothesis can be predicted in advance or when researchers are interested in results in a specific direction. This entry explains one-tailed tests in connection to other aspects of hypothesis testing and describes contexts in which one-tailed tests are the appropriate type of hypothesis testing.

Alternative Hypotheses: Directional Versus Nondirectional

In hypothesis testing, null hypotheses (H_0) are tested against statistical alternative hypotheses (H_a). Alternative hypotheses can be set up as nondirectional or directional. A nondirectional H_a states that the parameter differs from the value in the null hypothesis with no indication of the direction of the difference. For example, given H_0 stating that the population mean for reading achievement is 100 ($H_0 : \mu = 100$), the nondirectional H_a states that the population mean is different from 100 ($H_a : \mu \neq 100$). Thus, the non-directional H_a does not specify if the population mean is greater or less than 100. On the other hand, a directional H_a not only states that the parameter deviates from the value in the null hypothesis but also specifies the direction of the deviation. For the aforementioned $H_0 : \mu = 100$, a directional H_a can be that the population mean is either greater than 100 ($H_a : \mu > 100$) or less than 100 ($H_a : \mu < 100$).

The type of hypothesis testing in which H_0 is tested against a nondirectional H_a is called a two-tailed test, whereas the one in which H_0 is tested against a directional H_a is called a one-tailed test. The procedures for

conducting one- or two-tailed tests are fundamentally similar. The difference between one- and two-tailed tests lies in the location of the region of rejection in sampling distributions.

Each hypothesis testing, whether one-tailed or two-tailed, starts with setting up the null and alternative hypotheses before collecting data. Thus, researchers need to decide whether they will conduct a one-tailed or a two-tailed test before data collection. The second step in hypothesis testing that takes place before data collection is deciding the level of significance, alpha value. The level of significance is the probability of rejecting H_0 when it is actually true (i.e., the probability of Type I error). As with other probability values in hypothesis testing, alpha is obtained from sampling distributions. For a statistic of interest (e.g., $\bar{X}$ or SD), a sampling distribution is a distribution of an infinite number of sample statistics where the samples are the same size random samples as the actual sample from a population where H_0 is true. In a sampling distribution, the proportion of the area covered by any range of sample statistics represents the probability of that range of sample statistics obtained for a random sample from a population where H_0 is true. Accordingly, the alpha value represents the proportion of the area in a sampling distribution that is equal to the probability of Type I error. For example, for a sample of size 50, if the probability of Type I error is 5%, in the sampling distribution, which consists of means for every random sample of size 50, the area covered by the range of values that correspond to Type I error is 5% of the whole area. The area represented by alpha is also referred to as the *region of rejection*.

Region of Rejection

After data collection, a sample statistic is calculated for the sample in hand. The hypothesis testing proceeds to obtain the probability of the observed statistic or a more extreme one on a random sample from a population where H_0 is correct, which is called the p value. If the p value is less than the alpha level, then H_0 is rejected in favor of H_a . If the p value is larger than the alpha, H_0 fails to be rejected.

The sample statistic values for which the null hypothesis is rejected lie in the region of rejection. The region of rejection consists of sample statistics that are highly unlikely if the null hypothesis were true. In other words, the region of rejection consists of sample statistics that are extreme values of the alternative hypothesis. Thus, the region of rejection is directly related to the alternative hypothesis. For example, in a one-tailed test where H_0 is $\mu = 100$ and H_a is $\mu > 100$, the region of rejection is located in the right tail of the sampling distribution. The

sample statistics in the region of rejection are larger than 100 sufficiently enough to be considered highly unlikely at .05 level of significance if observed in a sample belonging to a population where H_0 is true. In the case of a one-tailed test where H_0 is $\mu = 100$ and H_a is $\mu < 100$, the region of rejection is located in the left tail of the test statistic sampling distribution. The sample statistics in the region of rejection are smaller than 100 sufficiently enough to be considered highly unlikely at .05 level of significance if observed in a sample belonging to a population where H_0 is true.

The area of the region of rejection is determined by the alpha level that is set at the onset of a study. For example, if the alpha level is set at .05, the region of rejection covers 5% of the total area in the sampling distribution.

Example

A heuristic example is used to explain the procedures for a one-tailed test. Although the sampling distribution and the sample statistics will differ, steps used in this example for conducting a one-tailed test can be generalized to other hypothesis-testing situations. This example compares male and female students' technology acceptance levels. The first step in one-tailed hypothesis testing is setting up H_0 and H_a even before data collection:

$$H_0: \text{The population means are the same} \\ (\mu_{\text{female}} - \mu_{\text{male}} = 0).$$

$$H_a: \text{The mean for females is greater than the mean for} \\ \text{males } (\mu_{\text{female}} > \mu_{\text{male}}).$$

Because the H_a states that μ_{female} is *larger* than μ_{male} , we are interested in the right-hand tail of the sampling distribution. In other words, the critical region for rejecting the null hypothesis lies in one (i.e., right) tail of the distribution. In one-tailed tests, the direction of the inequality in H_a determines the location of the region of rejection. If the inequality is $>$ in H_a , the region of rejection is in the right tail of the sampling distribution. If the inequality is $<$ in H_a , the region of rejection is in the left tail of the sampling distribution.

The second step in hypothesis testing involves deciding the alpha value as the criterion for rejecting H_0 . In this example, alpha was set at .05. The region of rejection, which constitutes sample statistics that are highly unlikely if the null hypothesis were true, covers 5% of the total area of sampling distribution and lies in the right tail.

Then, researchers collect data on 20 female and 20 male students. In these samples, the mean technology

acceptance levels for females and males were 100 and 70, respectively. Thus, the difference in sample means is $100 - 70 = 30$. It is important to note that when obtaining the difference in the sample means, we subtracted μ_{male} from μ_{female} , keeping the order in H_a . Hypothesis testing proceeds to evaluate if a difference of 30 in the sample means is large enough to reject the H_0 that the means do not differ in the population. Therefore, the probability (i.e., $p_{\text{calculated}}$) of obtaining such a difference or a more extreme one in a population where H_0 is true will be obtained.

To determine the $p_{\text{calculated}}$, the sampling distribution of the differences between two sample means will be used. With the sampling distribution, first a standardized score that quantifies the difference between the sample statistic and the hypothesized population parameter (i.e., test statistic) will be obtained. In this example, the sampling distribution of mean differences is derived assuming the mean difference in the populations is zero, which was stated in the null hypothesis as $\mu_{\text{female}} - \mu_{\text{male}} = 0$. The test statistic that will be used to compare the mean differences is the t statistic. A general formula for the t statistic is

$$t \text{ statistic} = \frac{\text{Sample statistic} - \text{Hypothesized parameter}}{\text{Standard error of the statistics}}.$$

For this example, assuming the standard error of the mean differences is 10, the t statistic is as follows:

$$t = \frac{(100 - 70) - 0}{10} = 2.0.$$

We can interpret a t statistic of 2.0 as a mean difference of 30 in the sample is 2.0 standard deviations away from the hypothesized population mean difference, which is zero.

In the last step of the hypothesis testing, researchers can determine the p value, which is the probability of obtaining a t statistic of 2.0 or more in a population where H_0 is true. Because, in this example, a one-sided H_a is used, only the probability of $t \geq 2.0$ is needed. Using a commonly available t -statistic sampling distribution, the probability of $t \geq 2.0$ is approximately .02625, which is smaller than the alpha value of .05. Because the p value is smaller than the alpha, the decision about H_0 is "reject."

One-Tailed Versus Two-Tailed Tests

In the above example, if a two-tailed hypothesis testing were conducted, the alternative hypothesis would be $\mu_{\text{female}} \neq \mu_{\text{male}}$. Because in a two-tailed test, the alternative

hypothesis does not have a direction, when researchers determine $p_{\text{calculated}}$, they consider not only obtaining such a difference or *more* in a population where H_0 is true but also obtaining such a difference or *less* in a population where H_0 is true. Thus, when a two-tailed H_a is used, both the probability of $t \geq 2.0$ and $t \leq 2.0$ are needed. Because t -distributions are symmetrical, the probability of $t \leq 2.0$ is approximately .02625 also. Therefore, the probability of $t \leq 2.0$ or $t \geq 2.0$ (i.e., p value) is around $.02625 + .02625 = .052$, which is larger than the alpha value of .05. Because the p value is larger than the alpha in the two-tailed case, the decision about H_0 is “fail to reject.”

As seen in the above example, the decision about H_0 may differ when a two-tailed rather than a one-tailed test is used. One-tailed tests provide more power to detect effects in one direction than do two-tailed tests. The increased power of one-tailed tests is due to the fact that the rejection region for a one-tailed test is located in only one of the tails of the sampling distribution. In other words, the probability of an effect in the opposite direction is ignored. Thus, the $p_{\text{calculated}}$ in a one-tailed test is smaller than the $p_{\text{calculated}}$ for a two-tailed test (e.g., is a symmetric sampling distribution, the $p_{\text{calculated}}$ in a one-tailed test is half as much as the $p_{\text{calculated}}$ in a two-tailed test). If researchers have theoretical bases to expect a difference in only one direction, one-tailed tests would provide them with more power. However, if researchers lack such a theoretical base, they should be careful about not using one-tailed tests just because one-tailed tests provide more power. Because one-tailed tests are more likely to provide statistically significant results, one-tailed tests without a theoretical base should be taken with a grain of salt. Another cautionary remark about using one-tailed tests in the absence of a theoretical base is that if sample statistics yield an effect in the opposite direction from the one-sided H_a , the null hypothesis will not be rejected.

OPERATIONALIZING

Operationalizing is a process in quantitative research whereby a concept or abstract idea, such as “stress,” is translated to a measurable and interpretable form. It involves clarifying the scope and dimensions of a concept (conceptual definition) and the development of indicators to capture those dimensions (operational definition). Operationalization can occur both before and after data collection. Careful consideration must be given to operationalization of a concept as it will have implications for analysis outcomes such as prevalence estimations, associations with other variables, and generalizability of the results. This entry presents the process and considerations for operationalizing concepts for research purposes, integrated with examples of operationalizing both at the data collection and analysis phases.

Conceptual Definition

Consulting the scientific literature to see how the concept has been defined or measured previously and examining what theory says defines the concept are the most common ways to commence operationalizing a concept. A theory is an overarching perspective or set of principles, such as social psychology or feminist theory, used to explain observable phenomena. Theory can help define the features and nature of single concepts according to those principles. The conceptual definition sets out *what* it is precisely that the researcher would like to measure. Where a concept is yet to have a standard definition, or the previously deployed definitions do not capture the perspective required for the research, it would be necessary to conduct some formative research to arrive at a conceptual definition. Often this would involve qualitative research methods where perhaps people are interviewed (for example, to define “research coproduction,” those who are working in collaborative partnerships may be interviewed to define what coproduction means to them). Alternatively, it may be more appropriate to use a Delphi technique, where experts in the field are interviewed and surveyed in several rounds of consultations to define the limits and dimensions of a concept and a definition is reached by consensus. An example is consulting experts in social media analysis to define “engagement” in social media use.

Operational Definition

Once the conceptual definition has been arrived at, the dimensions are translated into observable (either

subjectively or objectively) and measurable indicators. In other words, the operational definition describes *how* to measure the concept. Using previously validated and reliable indicators of the relevant conceptual dimensions is preferable as long as they meet the research purpose they are being put to. An indicator is considered to be validated if it has been tested and found to accurately and comprehensively capture the concept, while it is considered reliable if it has been tested and found to capture the concept consistently.

Capturing a concept may result in a singular indicator. Other concepts may require a series of indicators to cover a multidimensional definition. For example, a person's height is relatively straightforward to operationalize because it is a unidimensional, widely agreed upon phenomenon and has ready metrics (centimeters and inches) to draw on. By contrast, the conceptual definition of "stress" may identify physical, emotional, and cognitive dimensions, and therefore operationalization would require a number of indicators in order to capture all of these dimensions. Other concepts may be more complex to operationalize because there is disagreement or variation in conceptual definitions, and identifying salient aspects that require operationalization will depend on the research context and question. For example, measuring "leadership" as a component of successful community partnerships for health promotion would likely involve different indicators than "leadership" measured as a predictor of employee well-being.

Operationalization Before and After Data Collection

In some cases, how a variable is measured at data collection may require no further manipulation in order to be operationalized for analysis and reporting. In other cases, the data may be further manipulated in order to meet the needs of the research question. For example, when examining the research question of whether a *healthy diet* is associated with lower risk of heart disease, the concept of *healthy diet* may be operationalized at the data collection stage as self-reported number of servings (defined for the respondent) of fruit and vegetables consumed on average per day in the last week. The predictor variable of *healthy diet* is therefore operationalized as the raw count of servings of fruit and vegetables with increasing servings representing greater healthiness. Alternatively at the analysis stage, it may be more relevant to nutrition policy to further process the raw total number of servings by applying agreed upon thresholds such as the officially recommended levels of fruit and vegetable consumption. In this way, *healthy diet* is operationalized as meeting a guideline, a dichotomous (two-category variable)

representation linked to an externally defined but meaningful criterion.

Other forms of operationalization at the analysis stage may be driven by the data itself and include creating categories by, for example, splitting scores at the median (middle ranked value) or standardizing continuous scores to the number of standard deviations from the mean.

Implications for Research Outcomes

How a concept is operationalized can produce very different study outcomes in terms of the prevalence of a phenomenon and associations between predictors and outcomes. For example, a commonly used method of operationalizing "physical activity" in health research is to measure the frequency and duration of *activity* lasting at least 10 minutes or more. If a conceptual definition for physical activity includes only activity that is done *for the purpose of exercise*, a measure derived from this will produce different levels of physical activity than a measure derived from a conceptual definition that also includes incidental physical activity such as walking to get from one destination to another. Similarly, operationalizing physical activity in children as "bouts of continuous activity of 10 minutes" will not accurately reflect their physical activity levels because children tend to be active in frequent but short bursts. If activity intensity (low, moderate, vigorous) is included in the measure along with frequency and duration, this will result in different associations with health outcomes compared with a definition that does not take intensity into account. The choice of what is appropriate will come down to the research question being answered and the fit to the study sample and context, but researchers should explore the implications of those choices before making a final selection.

ORDER EFFECTS

In presenting information to individuals or groups, or in assessing how individuals or groups feel or think about an issue, researchers face the possibility that the order of materials might have a significant influence on the behavior, decisions, or evaluations of interest. A number of research streams have developed over the years to address these issues, known as order effects, as they are of interest for both practical (e.g., the desire to reduce bias in responses) and theoretical reasons (e.g., testing theoretical notions about the stability or strength of attitudes).

In persuasion research, message and argument order effects refer to changes in the influence of messages and arguments on attitude when the order of messages or argument presentation is varied. In survey research, two types of order effects are often observed: question order effects and response order effects. A question order effect refers to cases where exposure to or answering an earlier question affects the response to a later question. A response order effect refers to cases where the probability of an option being chosen changes depending on where it is placed in the list of options.

Message and Argument Order Effects in Persuasion Research

In the classic message order effect research by Carl Iver Hovland and his colleagues, primacy effects were said to be observed when the first of two opposing messages carried the greatest weight in some final judgment. Recency effects were said to be observed when the second of two opposing messages carried the greatest weight in a final judgment. In another line of research, Hovland and colleagues examined the persuasive influence of the order of information in a single persuasive message.

Most recent findings and reviews of the literature suggest that the motivation level with which an individual processes a first message is an important consideration. In general, primacy effects are more likely to be observed when a first message is processed under high levels of motivation and elaboration (i.e., when the person forms a strong attitude when exposed to the

first message). Recency effects are more likely when the first message is not processed extensively. Specific task instructions can reduce the likelihood of primacy effects (e.g., considering the information in chunks rather than piecemeal).

The line of research regarding argument order effects within a single message, along with the message order effect research, has focused on the persuasive outcome of exposure to materials. General results show that arguments presented first tend to have greater impact, especially when the list of arguments is presented verbally. More recent research suggests that individuals hold expectations about the order in which arguments are presented. Arguments are more effective when they are presented at positions where most important arguments are expected.

Question and Response Order Effects in Survey Research

Surveys are conducted to obtain measures of attitude, behavior, and/or memories of past behaviors that are as accurate representations of reality as possible. Two types of order effects are often encountered in survey research. One type is observed when answers vary when question order is changed, and the other type is observed when the order of response alternatives leads to different choices by respondents. Both question order effects and response order effects challenge the validity of survey data and generate intense interest in systematic research into the underlying causes of such effects.

One of the earliest examples of question order effect came from a survey on Americans' opinion on allowing U.S. citizens to join the German versus British or French army prior to America's involvement in World War II. Americans were more receptive of allowing U.S. citizens to join the German army if the question was asked after they had answered the same question on allowing U.S. citizens to join the British or French army. In another example, survey respondents reported their views on whether or not it should be possible for women to obtain legal abortion under two scenarios: when there is a strong chance for birth defect (birth defect item) and when the woman is married but does not want to have more children (married-woman item). When the birth defect item comes first, there was less support for pro-choice on the married woman item.

Since the 1950s, survey researchers have documented many examples in which question order altered responses to the target question. Reviews of the literature suggest that a variety of social, cognitive, and motivational processes affect how respondents comprehend the survey question, retrieve relevant information,

form judgments, map judgments to response categories, and edit responses before giving out answers.

First, surveys can be viewed as structured conversations between researchers and survey participants. As with ordinary conversations, speakers are supposed to be truthful, relevant, informative, and clear. Unless instructed otherwise, survey respondents will likely follow these conversational norms in interpreting the meaning of questions and deciding what information is sought by the researcher. Thus, they may decide to exclude information already provided through earlier questions from their judgment in answering later questions in an attempt to be informative. Changes in question order can lead to the exclusion of different information from later judgment, thus producing variations in response.

Second, survey respondents use a variety of information to infer the intended meaning of questions and forming judgments. Previous questions can serve as a frame of reference and affect respondents' interpretation of later questions. Answering preceding questions may also make related information more accessible in memory and more likely to be used in forming judgments in later questions. Answering questions can also produce changes in mood and perceptions of how easy or difficult it is to recall relevant information. Such changes in subjective experience can confound reported judgments. In addition, answering a question may increase the accessibility of certain procedural knowledge or decision strategies that may then be used in answering later questions.

Third, answers to a previous question may also trigger differing degrees of motivational processes. In the previous example on granting U.S. citizens permission to enlist in the German army, the majority of survey respondents felt it was okay to let U.S. citizens join the friendly armies of Britain and France. Having expressed this sentiment, they would feel compelled to grant similar permission to those who wish to join the German army because denying them would be perceived as a violation of the social norm of fairness. When asked outright about their opinion to grant permission to individuals seeking to enlist in the German army, survey respondents were unlikely to be affected by the motivation to be fair; thus, their responses tended to be less positive.

Most individuals are motivated to hold beliefs that are cognitively consistent and prefer others to see them as being consistent in their ideas and opinions. Answers to previous questions may commit a respondent to a particular position and create pressure to appear consistent when answering later questions.

In addition to question order effects, response order effects are also frequently observed in mail and telephone surveys. In mail surveys, survey participants tend to choose the option at the beginning of the list with greater frequency than the option at the end of the list.

In telephone surveys, when the options are presented verbally, participants tend to choose the option at the end of list with greater frequency. Such differences have been attributed to limitations of working memory capacity and a general tendency of respondents to choose an acceptable answer instead of the most appropriate answer.

As the brief review above suggests, the order in which messages, arguments, questions, or options for answers are presented can have significant influence on the data obtained from participants. It is thus important for social scientists to consider and study the influence of such variables in their own applications.

ORDINAL SCALE

In the hierarchy of measurement levels, the ordinal scale is usually considered the second lowest classification order, falling between the nominal and interval scales. An ordinal scale is a measurement scale that allocates values to variables based on their relative ranking with respect to one another in a given data set. Ordinal-level

measurements indicate a logical hierarchy among the variables and provide information on whether something being measured varies in degree but does not specifically quantify the magnitude between successive ranks. The measurement taxonomy, including the ordinal scale terminology, was first brought forth by psychologist Stanley Smith Stevens in his 1946 seminal paper and has subsequently guided the selection of appropriate statistical techniques despite debates on its limitations, data exceptions, and contemporary relevance.

Ordinal-scale variables may be further classified as strongly ordered or weakly ordered (as presented by J. Chapman McGrew Jr. and Charles Monroe) depending on the ranking scheme. A strongly ordered variable is one in which the measurements are continuous, sequentially ordered, and not strictly categorically dependent. For example, a list of the 10 most populous countries in the world receive rankings based on their relative population size to one another, demonstrating an order then from highest to lowest; however, as with all ordinal-level data, the exact difference in population between successive rankings would be unknown. On the other hand, a weakly ordered variable is based on nominal-level groups that are then rank-ordered in a meaningful arrangement. These groups represent frequency counts and do not display individual rankings of the aggregated data, thus limiting the amount of information conveyed when compared with strongly ordered variables. Categories showing country population as low (less than 1 million), medium (between 1 million and 100 million), and high (greater than 100 million), for instance, are weakly ordered because rankings within the ordered categories cannot be differentiated.

Numeric measurements on ordinal scales are ordered such that higher (lower) rankings are associated with larger (smaller) values. A common ordinal scale frequently employed in social and behavioral research is the Likert scale, which uses a hierarchical ranking system to indicate comparative levels of satisfaction, confidence, agreement, and so on about a subject. Many mental constructs in psychology cannot be observed directly; therefore, these measures tend to be ordinal (e.g., Likert scaling). Opinions, attitudes, level of anxiety, specific personality characteristics, and so on are all constructs that are regarded as varying in degree among individuals but tend to allow only indirect ordinal measurements. These are generally self-report measures. For example, a subject might be asked to rate the level of satisfaction he or she experiences with his or her current job on a Likert scale from 1 (*extremely dissatisfied*) to 5 (*extremely satisfied*). It cannot be assumed that a person assigning a rating of "4" to that question is exactly twice as satisfied with his or her job as a co-worker who answers the question with a "2."

However, it is clear that the first person feels more satisfied with his or her job than the co-worker.

Providing rankings is also a common type of ordinal scale. For example, a subject might be asked to rank a list of values according to what is most important to him or her. Another example is a faculty search committee asked to rank-order a list of job candidates based on the overall qualifications in the areas of teaching ability, research skills, and so on. The candidate ranked "1" will be perceived by the committee as better than the candidate ranked "2" but not how much better. A special case of the ordinal scale occurs when data are used to classify individuals into two categories (a dichotomy), but the variable itself is assumed to be normally distributed with underlying continuity. For example, a psychological test might classify individuals into the categories *normal* (1) or *abnormal* (0). There is an implied order in the presence or absence of a characteristic.

As with other measurement scales, statistical methods devised to explicitly use ordinal-level data differ from approaches employing data in the nominal, interval, or ratio scales. Descriptive statistics, such as the median, range, and mode, can be determined for ordinal-level data in the same way as other measurement scales, but mean and standard deviation are not appropriate for ordinal data. This is because the numeric values are based on an arbitrarily defined starting point, and the distance between rankings is not identified. Correlation coefficients indicate the degree of relationship between one variable and another variable. The appropriate correlation coefficient for two ordinal-scale variables is the Spearman rank correlation coefficient or Spearman rho (ρ). Other correlations that include one variable at the ordinal level and the other variable at another level of measurement include rank-biserial (nominal and ordinal) and biserial (ordinal and interval/ratio). Several appropriate tests of significance are available for the one-sample case for ordinal data, including the Mann-Kendall tests for trends and the Kolmogorov-Smirnov one-sample test. Several nonparametric tests of significance are available for the two-sample case of ordinal data with independent samples, including the median test and the Mann-Whitney U test. In a multiple sample case with ordinal data, the Kruskal-Wallis one-way analysis of variance test is used. For example, a researcher might want to know if actors, musicians, and painters differ on a ranking of extroversion. The null hypothesis tested is that the population distributions from which the samples were selected are the same. If samples are dependent for ordinal data, the appropriate statistical test of the two-sample case would be the Wilcoxon matched-pairs signed-rank test.

ORTHOGONAL COMPARISONS

The use of orthogonal comparisons within an analysis of variance is a common method of multiple comparisons. The general field of multiple comparisons considers how to analyze a multitreatment experiment to answer the specific questions of interest to the experimenter. Orthogonal comparisons are appropriate when the researcher has a clearly defined, independent set of research hypotheses that will constitute the only analyses done on the treatment means. Of the multiple comparison techniques available with comparable control over Type I error (rejecting a true null hypothesis), a set of orthogonal comparisons will provide a more powerful approach to testing differences that may exist between the treatment groups than those that are more exploratory in nature and thus more extensive. The power is gained by restricting the analysis to a small number of preplanned, independent questions rather than exploring for whatever difference may be present in the data.

Basic to an understanding of orthogonal comparisons is the concept of a comparison within a multi-group analysis of variance. Assume a balanced design in which each treatment group has an equal number of subjects. The great majority of comparisons deal with either differences between pairs of means, such as whether Group 1 differs from Group 2, or the differences between combinations of means, such as whether the average of Groups 1 and 2 differs from the average of Groups 3 and 4. This latter type of compound hypothesis, involving combinations of groups, is common in orthogonal comparisons. It is appropriate when groups have common elements that make the combination a meaningful grouping. If a learning experiment involves treatment groups that differ with respect to the type of prompts provided to students, there may be

some groups that have in common that the prompts are delivered verbally, although they differ in other respects. Other treatment groups may have the prompts delivered in written form, again differing in other respects. A compound question focuses on the overall difference between the verbally delivered prompts and those where the prompts were delivered in writing.

The comparison is conceptualized as a set of weights, one for each of the k treatment groups, $a_i = \{a_{i,1}, a_{i,2}, \dots, a_{i,k}\}$, whose sum must be zero and whose pattern reflects the question being addressed. For example, the set $\{1 - 100\}$ in a four-group experiment is a comparison because $\sum a = 0$. It would be used to compare the first group with the second group, ignoring the third and fourth groups. A different comparison is defined by the weights $\{1, 1, -1, -1\}$, which also sum to zero and combine the first two groups and compare that sum with the sum of the last two groups. The important information in a set of weights is the pattern. The set $\{1/2, 1/2, -1/2, -1/2\}$ has the same pattern and would produce equivalent results to the set $\{1, 1, -1, -1\}$.

The null hypothesis for a comparison asserts that the sum of the products of weights multiplied by the population means is zero. Call this sum of products ψ . The null hypothesis is that

$$\psi = a_{11}\mu_1 + a_{12}\mu_2 + \dots + a_{1k}\mu_k = 0 \quad (1)$$

or, for the example above with four treatment groups,

$$\psi_1 = (1)\mu_1 + (1)\mu_2(-1)\mu_3 + (-1)\mu_4 = 0. \quad (2)$$

If the null hypothesis is true and the overall effect of the first two groups is the same as that of the last two, the sample-based estimate of,

$$\hat{\psi}_1 = (1)\bar{X}_1 + (1)\bar{X}_2 + (-1)\bar{X}_3 + (-1)\bar{X}_4 \quad (3)$$

will randomly differ from zero. Tests of significance based on the probability of $\hat{\psi}_1$, given the null hypothesis that $\psi = 0$, can be evaluated using either the t test or F test with identical outcomes.

The concept of orthogonality is relevant when an experiment has more than one comparison. Experiments with multiple groups typically have a number of questions that are of interest. Groups that are combined in one comparison may be compared or combined in a different way in another. The particular set of comparisons chosen must reflect the specific questions of interest to the experimenter.

Imagine an experiment in which two specific comparisons are of interest. An issue of importance concerns the relationship between the two comparisons. The major distinction is between pairs of comparisons that are orthogonal and those that are not. The condition of orthogonality refers to the degree of

independence of the questions. Comparisons that are orthogonal are independent and thus uncorrelated. They account for separate aspects of the total amount of variability between the means. The indication that two comparisons are orthogonal is that the sum of the products of the corresponding weights is zero (e.g., $\sum a_{1,j} a_{2,j} = 0$). The weight for Group 1 from Comparison 1 is multiplied by the weight for that group from Comparison 2. In a like manner, the weights for Groups 2 through k for Comparison 1 are multiplied by the corresponding weights for Comparison 2. These products are then summed. Only if the sum of these products is zero are the comparisons said to be orthogonal.

Assume that there is a comparison of interest defined by the weights $a_1 = \{1, 1, -1, -1\}$. For this particular comparison, a number of additional comparisons (a_2) could be investigated that would be orthogonal to it. One of these is the comparison defined by $a_{2a} = \{1, -1, 0, 0\}$, which would look at the difference between the first two groups, a difference obscured in the first comparison by summing Groups 1 and 2 together. The sum of the products of the weights for these comparisons is $\sum a_{1,j} a_{2a,j} = (1)(1) + (1)(-1) + (-1)(0) + (-1)(0) = 0$. Another comparison with weights of $a_{2b} = \{1, -1, 1, -1\}$ would also be orthogonal to a_1 as the sum of the products of weights is zero [e.g., $\sum a_{1,j} a_{2b,j} = (1)(1) - (1)(-1) + (-1)(1) + (-1)(-1) = 0$]. Additional comparisons would form an "orthogonal set" if each comparison were mutually orthogonal to each of the other comparisons in the set. There is no single test for a set of mutually orthogonal comparisons. Rather, an orthogonal set is one in which the sum of the products for each pair of comparisons is zero.

Comparisons that are nonorthogonal share common variability in that they share a portion of a common pattern. For example, $a_1 = \{1, 1, -1, -1\}$ and $a_{2c} = \{1, 0, -1, 0\}$ both involve the difference between the first and third groups, in one case including Groups 2 and 4, and in the other, ignoring these groups. The sum of products is $\sum a_{1,j} a_{2c,j} = (1)(1) + (1)(0) + (-1)(-1) + (-1)(0) = 2$. Because the sum is not zero, the comparisons are not orthogonal.

Because of the mutual independence of the comparisons within a set of orthogonal comparisons, the possible number of comparisons contained within any specific set is limited to $k - 1$, the number of independent pieces of information or degrees of freedom associated with the sum of squares between groups. The sum of squares associated with a comparison is a part of the sum of squares between groups. In a complete set of $k - 1$ orthogonal comparisons, the sum of squares between groups will be partitioned into $k - 1$ comparison sums of squares, each with one degree of freedom, that add up to the sum of squares between groups.

In the example above, both $a_{2a} = \{1, -1, 0, 0\}$ and $a_{2b} = \{1, -1, 1, -1\}$ were orthogonal to $a_1 = \{1, 1, -1, -1\}$, but they are not orthogonal to one another (e.g., $\sum a_{2a,j} a_{2b,j} = 2$), so they do not form an orthogonal set. Because our example has $k = 4$ treatment groups, a complete set would have $k - 1 = 3$ comparisons. The partial sets defined by a_1 and a_{2a} and by a_1 and a_{2b} would have different third comparisons that uniquely complete the set. In the first case, the weights would be $a_{3a} = \{0, 0, 1, -1\}$, which would complete a hierarchical set, and in the second partial set, the weights would be $a_{3b} = \{1, -1, 1, -1\}$, which is part of a factorial set (see below).

Each comparison has a separate test of significance. Experimentwise (familywise) α Type I error control over the $k - 1$ comparisons in a complete set of orthogonal comparisons can be maintained by using a modification of Bonferroni's inequality by Zbynek Sidak. Per comparison control is sometimes reported, in which each comparison is evaluated at an α Type I error rate. The justification for this more liberal control rests on the small number of comparisons conducted, their independences, and their being planned prior to the conduct of the experiment.

Although the specific choice of orthogonal comparisons must reflect the interests of the researcher, there are several standard patterns. The following illustrations are based on $k = 4$ treatment groups. In a factorial design, if all treatment factors have 2 levels, the main effects and interaction(s) are a set of orthogonal comparisons. In a 2×2 with treatment groups $A_1B_1, A_1B_2, A_2B_1, A_2B_2$, the A main effect, B main effect, and $A \times B$ interaction would be given by the weights $\{1, 1, -1, -1\}$, $\{1, -1, 1, -1\}$, and $\{1, -1, -1, 1\}$, respectively. A hierarchical set consists of a compound comparison involving two combinations of groups. The remaining comparisons explore differences within the combinations. An example set of weights would be $\{1, 1, -1, -1\}$, $\{1, -1, 0, 0\}$, and $\{0, 0, 1, -1\}$. A Helmert set consists of a series of comparisons in which a single treatment group is compared with the remaining groups combined. The basic strategy of comparing one group to a combination of groups continues with the previous single group omitted. For four treatments, the weights would be $\{3, -1, -1, -1\}$, $\{0, 2, -1, -1\}$, and $\{0, 0, 1, -1\}$. The last common type is a set of orthogonal polynomials. The comparisons test for linear, quadratic, and higher order trends in the treatment means where the highest order in a particular set is $k - 1$. This set is specifically designed for treatments where the groups differ by amount rather than kind of treatment. With four treatments, it would be possible to test for linear, quadratic, and cubic trends. The weights would be $\{3, 1, -1, -3\}$, $\{1, -1, -1, 1\}$, and $\{1, -3, 3, -1\}$. Note that in all of these sets, there are $k - 1$ or three comparisons as there are $k = 4$ treatments.

A complete set of orthogonal comparisons provides an elegance of design in which all of the variability in the means is accounted for somewhere within the set of only $k - 1$ comparisons. However, there are occasions in which one or more additional comparisons may be needed to provide a satisfactory analysis of the data. This expanded set can be accommodated by using the critical value from Sidak that reflects the increased number of comparisons actually tested.

Orthogonal comparisons impose strict conditions on the number and nature of the comparisons within an experiment. For many experiments, orthogonal comparisons are too restrictive and do not allow the researcher to explore the many possible ways in which groups might differ. However, when the experimenter is willing to limit the questions asked to an orthogonal set of only $k - 1$ comparisons, it will translate into increased power and a more parsimonious description of the differences present.

OUTLIER

An outlier is an observation in a set of data that is inconsistent with the majority of the data. An observation (i.e., score) is typically labeled an outlier if it is substantially higher or lower than most of the observations. Because, among other things, the presence of one

or more outliers can dramatically alter the values of both the mean and variance of a distribution, it behooves a researcher to determine, if possible, what accounts for their presence. An outlier can represent a valid score of a subject who just happens to represent an extreme case of the variable under study, it can result from failure on the part of a subject to cooperate or follow instructions, or it can be due to recording or methodological error on the part of the experimenter. If the researcher has reason to believe that an outlier is due to subject or experimenter error, he or she is justified in removing the observation from the data. On the other hand, if there is no indication of subject or experimental error, the researcher must decide which of the following is the most appropriate course of action to take:

- a. Delete the observation from the data. One disadvantage associated with removing one or more outliers from a set of data is reduction of sample size, which in turn reduces the power of any statistical test conducted, although in the case of commonly employed inferential parametric tests (e.g., t test and analysis of variance), the latter may be counteracted by a decrease in error variability.
- b. Retain the observation, and by doing so risk obtaining values for one or more sample statistics that are not accurate representations of the population parameters they are employed to estimate.
- c. Retain one or more observations that are identified as outliers and evaluate the data through the use of one of a number of statistical procedures that have been developed to deal with outliers, some of which are discussed in the last part of this entry.

Strategies for Identifying Outliers

One strategy for identifying outliers employs a standard deviation criterion that is based on Chebyshev's inequality, which states that regardless of the distribution of a set of data, $[1 - (1/k^2)](100)$ percent of the observations will fall within k standard deviations of the mean (where k is any value greater than 1). Because the percent values computed are quite high when k is equal to 2, 3, 4, and 5 standard deviation units (respectively, 75%, 88.89%, 93.75%, and 96%), it indicates that scores that are beyond two standard deviations from the mean are relatively uncommon, and scores that are three standard deviations and beyond from the mean are relatively rare. However, employing a standard deviation criterion (e.g., declaring any observation that is three or more standard deviations from the mean an outlier) can be misleading sometimes, especially with small sample sizes and data sets with anomalous configurations.

Another tool that can be employed for identifying outliers is a box-and-whisker plot (also referred to as a *boxplot*), which is a visual method for displaying data developed by the statistician John Tukey. Typically, in a box-and-whisker plot, any value that falls more than one and one-half *hingespreads* outside a *hinge* can be classified as an outlier, and any value that is more than three hingespreads as a *severe outlier*. The value of a hingespread is the difference between the lower and upper hinge of the distribution. In a large sample, the upper and lower hinges of a distribution will approximate the 25th and 75th percentiles.

A final strategy for identifying outliers is to conduct an inferential statistical test. More than 50 different tests have been developed, most of which assume that a set of data is derived from a normal distribution. Some tests identify only the presence of a single outlier, whereas others are capable of identifying multiple outliers. Some tests are specific with respect to identifying outliers in one or both tails of a distribution. It should be noted that it is not uncommon for two or more tests applied to the same set of data to yield inconsistent results with regard to whether a specific observation qualifies as an outlier.

Strategies for Dealing With Outliers

As noted earlier, aside from deleting observations that are identified as outliers from a set of data, a number of other strategies are available. A strategy referred to as *accommodation* uses all of the data, yet minimizes the influence of outliers. The latter can involve use of a non-parametric test that rank-orders data and uses the median in lieu of the mean as a measure of central tendency. Another strategy is to evaluate the data with a *robust statistical procedure*, which is any one of more recently developed methodologies that are not influenced (or only minimally affected) by the presence of outliers.

Two other types of accommodation are *trimming* and *Winsorization*. Trimming involves deleting a fixed percentage of extreme scores from both the left and right tails of a distribution (e.g., the extreme 10% of the scores are removed from both tails). In Winsorization (named for the statistician Charles Winsor), a fixed number of extreme scores in a distribution are replaced with the score that is in closest proximity to them in each tail of the distribution. To illustrate, consider the following distribution of scores: 1, 24, 25, 26, 26, 28, 32, 33, 33, 36, 37, 39, 98. Winsorizing would be replacing the values 1 and 98 at the lower and upper ends of the distribution with the values closest to them, 24 and 39.

OVERFITTING

Overfitting is a problem encountered in statistical modeling of data, where a model fits the data well because it has too many explanatory variables. Overfitting is undesirable because it produces arbitrary and spurious fits, and, even more importantly, because overfitted models do not generalize well to new data.

Overfitting is also commonly encountered in the field of machine learning, including learning by neural networks. In this context, a learner, such as a classifier or an estimator, is trained on an initial set of samples and later tested on a set of new samples. The learner is said to be overfitted if it is overly customized to the training samples and its performance varies substantially from one testing sample to the next.

Because the nature of the overfitting problem and the methodologies of addressing it are fundamentally similar in the two fields, this entry examines overfitting mostly from the viewpoint of statistical modeling.

Relationship Between Model Fit and the Number of Explanatory Variables

In a statistical model, the fit of the model to the data refers to the extent to which the observed values of the response variable approximate the corresponding values estimated by the model. The fit is often measured using the coefficient of determination R^2 , the value of which ranges between 0 (no fit) and 1 (perfect fit).

As one adds new explanatory variables (or *parameters*) to a given model, the fit of the model typically increases (or occasionally stays the same, but will never decrease). That is, the increase in fit does not depend on whether a given explanatory variable contributes

Figure 1 Overfitting and Underfitting

Notes: These hypothetical clinical data show the blood levels of a biomarker B1 in a group of newborn infants measured during the first 50 weeks of their lives. Panels A and B are from the first group of babies (Sample 1), and the data in Panel C are from a different, independent sample. The dots represent the observed values of the biomarker (in arbitrary units). The thin black lines represent the underfitted and overfitted models (Panels A and B), respectively. The thick gray line in Panel B denotes the parsimonious model that best fits Sample 1. The same model is also shown in Panel C for comparison. Note that even though the model fits the data in Sample 1 rather well, it fails to predict the new data in Sample 2.

significantly to the overall fit of the model or adds to its predictive power. Therefore, all other things being equal, a larger number of explanatory variables typically means better fit, but it does not necessarily mean a better model.

How many variables are too many depends on the model and the data. There is no preset number of variables above which the model is considered overfitted. Rather, overfitting is a graded property of a model: A given model is more or less overfitted depending on the number of parameters it has relative to the number of parameters actually needed.

Why Overfitting Is Undesirable

The function of a statistical model is twofold: First, it should help account for, or explain, the observed values in the original sample(s) on which it is based. Second, and more importantly, it should reliably predict the observed values in new testing samples. Overfitting compromises both the explanatory and predictive abilities of a model.

To understand how, suppose one is interested in modeling the levels of a hypothetical biomarker in healthy babies as a function of the baby's age (Figure 1). Age-appropriate levels of the biomarker signify normal development. The goal of the modeling endeavor is to determine which factors affect the levels of this biomarker.

Figures 1a and 1b show the biomarker levels measured in one group of babies during the first 50 weeks of their lives. When baby's age is used as the sole

explanatory variable—that is, when the model underfits the data—the model is consistently “off the mark”; it generally misestimates the response variable (Figure 1a). In this case, the model is said to have high *bias*.

Figure 1b shows the same data overfitted by blindly using every last bit of information about the babies as explanatory variables—including age, gender, ethnicity, diet, and hours of sleep per day—up to and including clearly absurd variables such as the color of the diaper, number of traffic deaths during the given week, and the phase of the moon. This model, although manifestly absurd, fits the observed data from this sample nearly perfectly (Figure 1b). Yet the model explains little of the observed biomarker levels. That is, a good fit does not necessarily make a good model.

The model is whittled down to retain only those factors that can account for a statistically significant portion of the observed data. This more parsimonious model provides a reasonable approximation to the data (Figure 1b, thick gray line). Therefore, this model fulfills the first of its aforementioned functions: It helps explain the data at hand.

However, this model still does not provide a good fit to a new sample (Figure 1c). This is the second, larger problem with the overfitted models: Because they are overly customized to the original samples, they are not sensitive to data patterns that occur only in some of the samples if those patterns happen not to be present in the original samples. Therefore, they fail to generalize well across all samples, so that their degree of fit tends to vary from one sample to the next. Such models are

Figure 2 Model Selection as a Trade-Off Between Bias and Variability

Note: As the number of model parameters increases, the bias of the model decreases (dashed line), and the variance of the model increases (solid line). The point at which the two lines intersect represents the most optimal theoretical balance between underfitting and overfitting (i.e., optimal bias-variance trade-off) when all other things are equal.

said to have high *variance*. That is, the second model, although more parsimonious, is still overfitted.

Preventing Overfitting: The Principle of Parsimony

Clearly, a good model avoids both of these extremes of underfitting and overfitting. The general approach to building models that avoid these extremes is enunciated by the *principle of parsimony*, which states that a model should have the fewest possible number of parameters for adequate representation of the data. Achieving parsimony by “shaving away all that is unnecessary” is often referred to as *Occam’s razor*, after the 14th-century English logician William of Occam.

Bias-Variance Trade-Off

A principled, and widely used, approach to determining the optimal number of parameters in a model is to find the optimal trade-off point between bias and variance (Figure 2). As noted above, if the model has too few parameters (i.e., if it is underfitted), it tends to have a large bias. If it has too many parameters (i.e., if it is overfitted), it tends to have a large variance. Thus, the number of parameters that best balances bias with variance achieves the best balance between underfitting and overfitting.

It is important to note that the bias-variance trade-off represents only a conceptual guideline for preventing overfitting and not an actual methodology for doing it. This is because, for one thing, it is impossible to precisely determine the point of optimal trade-off with a finite number of samples and without knowing the “ground truth,” that is, what the “correct model” actually is. For another, the optimal balance between bias and variance often depends on many factors, including the goal of modeling. For instance, when simplicity of the model is paramount, a researcher may select the smallest number of parameters that still provide a significant fit to the data. On the other hand, when bias is more “costly” than variance, one may retain more parameters in the model than strictly necessary. Thus, a model that is not the most parsimonious is not necessarily a bad model.

Model Selection Methods

Just as there is no single, universally applicable definition of what a good model is, there is no single, universally acceptable method of selecting model parameters. Rather, there is a variety of available methods. The methods vary widely in how they operate and how effective they are in preventing overfitting. It is beyond the purview of this entry to survey them all. Instead, some main approaches are briefly outlined.

As noted above, one can start with an overfitted model and test each explanatory variable for whether it contributes significantly to the model fit at a given alpha level (e.g., 0.05) and retain it in the model only if it does. Alternatively, one can start with an underfitted model and incorporate only those variables that significantly improve the overall fit of the model. These step-up (or forward) versus step-down (or backward) parameter selection methods generally (although not always) produce largely similar models. Such significance-testing (or hypothesis-testing) methods, although widely used in the biological and social sciences, are considered inadequate by themselves for model selection. This is ultimately because these methods only address the ability of a given variable to explain the original data and do not test the ability of the model to predict new ones. *Cross-validation* addresses some of these shortcomings, where the selected model is tested against new samples.

Akaike’s Information Criterion (AIC) is an information theory-based index that measures the goodness of fit of a given model. It, along with its many variations, is a measure of the trade-off between bias and variance. For this and many other reasons, this measure has been a highly regarded method of preventing overfitting. Mallows’ C_p statistic is another goodness-of-fit measure

that generally, but not always, produces results similar to AIC.

Using Bayesian principles of inference is one of the most promising new approaches to the prevention of overfitting. In machine learning, Bayesian principles have been used in two main ways to prevent overfitting. First, prior marginal probability distribution of a given explanatory variable has been used to help infer the extent to which the variable “belongs” in the model. Second, model selection itself can be treated as a Bayesian decision problem, so as to select a model that is most likely to be the “correct” model. These techniques, however, are yet to be widely used for preventing overfitting in the biological and social sciences.

It should be clear from the foregoing discussion that preventing overfitting is as much an art as it is a science because it involves exercising subjective judgment based on objective statistical principles. The fact that the optimal model is often in the eye of the beholder means that model selection methods can be abused to select one’s favorite model. But such a fishing expedition of methods to support one’s favorite model is inappropriate. The researcher’s question ought to be which model best represents the data at hand and *not* which method supports the model of choice.

P

P VALUE

p values are calculated as a part of hypothesis testing, and p values indicate the probability of obtaining the difference observed in a random sample or a more extreme one in a population where the null hypothesis is true. Because of the widespread use of hypothesis testing, p values are a part of virtually all quantitative research reports. This entry explains p values in connection to other aspects of hypothesis testing and provides some cautions concerning the use of p values.

Hypothesis Testing

Hypothesis testing is one of the main methods used for statistical inference. In hypothesis testing, researchers set up a hypothesis about a population parameter(s) and, based on data from a random sample drawn from this population, test its tenability. The tested hypothesis is called the null hypothesis. Null hypotheses are represented by H_0 . Null hypotheses may specify a value or a range of values for population parameter(s), differences or relationships between population parameters, or an effect in the population. For example, H_0 can state that a population mean is 100 ($H_0 : \mu = 100$) or that the difference between two populations' means is greater than 50 ($H_0 : \mu_1 - \mu_2 > 50$). In the most common application of hypothesis testing, H_0 of no association, no difference, or no effect is used, and this type of H_0 is often referred to as a nil null hypothesis. An example of a nil null hypothesis might be that there is no difference between two population means ($H_0 : \mu_1 = \mu_2$).

The H_0 is tested against a statistical alternative hypothesis. If H_0 is rejected, the alternative hypothesis holds true for the population. Alternative hypotheses

are commonly symbolized as H_a , although some use other symbols, such as H_1 . Generally, H_0 is tested using data from a sample(s), however, both H_0 and H_a always refer to population parameters. For the H_0 that there is no difference between two population means ($H_0 : \mu_1 = \mu_2$), an H_a would be that these population means are not the same ($H_a : \mu_1 \neq \mu_2$). A nondirectional H_a about parameters is called a *two-sided* or *two-tailed* H_a . For example, $H_a : \mu_1 \neq \mu_2$ denotes a difference between two population means but does not indicate which of these means is larger or smaller. On the other hand, a one-sided or one-tailed H_a specifies the direction of the relationship. For the $H_0 : \mu_1 = \mu_2$, a one-sided H_a would be $H_a : \mu_1 < \mu_2$ or $H_a : \mu_1 > \mu_2$.

Often, H_a states researchers' expectations or assumptions about the study's outcome and is commonly referred to as the research hypothesis. In many cases, researchers would like to reject H_0 and hold H_a tenable for the population. However, this is not always the case. For example, when testing the effectiveness of a cheap drug compared to a more expensive drug, H_0 can be that the cheap drug's effectiveness is the same as the expensive drug's. In this situation, researchers probably would not want to reject the H_0 .

After establishing H_0 and H_a , data are collected from a sample and then used to test the tenability of the hypotheses about population parameters. The hypothesis that is tested is always H_0 , not H_a . The hypothesis testing process is a form of indirect proof—proof by contradiction. The testing process starts with the assumption that H_0 is true for the population. If the magnitude of the difference between the obtained statistic (e.g., $\bar{X}$ or SD) and the population parameter as stated in H_0 is highly unlikely to be observed in a sample belonging to a population where H_0 is true, then H_0 is *rejected* in favor of H_a . If the observed difference is not sufficiently unlikely, then H_0 is

considered to be tenable for the population, and researchers *fail to reject* H_0 . Notice that researchers either *reject* or *fail to reject* H_0 ; H_0 is never accepted because it is never proved, but rather the evidence may be insufficient to disprove it.

In hypothesis testing, researchers use a sample to infer about the population(s). However, every sample may or may not reflect the whole population. Therefore, researchers who have to rely on the sample statistic to reach a conclusion regarding the hypothesis about the population(s) face the probability of two types of errors:

Type I error occurs when H_0 is rejected in favor of H_a based on the sample statistics, when in fact, the H_0 is true in the population(s).

Type II error occurs when H_0 is not rejected based on the sample statistics, when in fact, the H_0 is false in the population(s).

As seen in Table 1, when researchers make a decision about rejecting or failing to reject H_0 , they face the probability of either a Type I or a Type II error, but not both. If H_0 is rejected, only Type I error probability should be considered, and if H_0 is not rejected, then only Type II error probability remains. Although it is desirable to eliminate both types of errors, this is not possible. However, hypothesis testing allows for controlling Type I error rate.

At the onset of a study, researchers choose a probability level for Type I error that they think is acceptable when consequences of an error are considered. Typically, if other variables remain constant, when Type I error probability decreases, Type II error probability increases, and vice versa. Therefore, when researchers specify a level for Type I error rate, they need to consider the consequences of both types of errors. For example, in a drug trial, incorrectly deciding that a new drug with serious side effects is more effective for improving patient survivability than a currently available drug with mild side effects—thereby committing a Type I error—can lead to exposing patients to serious side effects without any other health benefits. In

such a case, researchers are likely to set a low probability level for Type I error. On the other hand, in a study where a promising new instructional model is evaluated against traditional instruction, incorrectly deciding that the new model is no more effective than the traditional model—thereby committing a Type II error—may result in abandoning research in a favorable area. In such a situation, which does not involve dire consequences, researchers may opt for a greater probability of Type I error.

Level of Significance

The probability of Type I error in hypothesis testing is controlled by the chosen level of significance and is commonly represented by alpha (α) or p_{critical} . Alpha can range between 0 and 1 like any probability value and is chosen before data collection. The most commonly used alpha values are .05 and .01, although researchers can use other alpha levels as they consider Type I and Type II error consequences. An alpha of .05 means that the probability of making a Type I error (rejecting the H_0 when it is actually true) is 5%. Accordingly, an alpha of .01 means that there is a 1% probability of a Type I error. Alpha is used as the criterion for rejecting H_0 .

Probability values in hypothesis testing are obtained from sampling distributions. For the statistic of interest (e.g., $\bar{X}$ or SD), a sampling distribution is derived mathematically such that the distribution represents statistics from an infinite number of same-size random samples as the actual sample from a population where H_0 is true. The probability of any range of statistics on a random sample from a population where H_0 is true is equal to the proportion of the area covered by that range in the sampling distribution. For example, for a sample size of 30, if the probability of obtaining a mean of $100 < \bar{X} < 150$ is 5%, then in the sampling distribution, which consists of means for every sample at size 30, the area covered by the range of 100 to 150 is 5% of the whole area. The level of significance is the proportion of area in the sampling distribution that is equal to the probability of Type I error.

Table 1 Type I and Type II Errors

Statistical Decision	State of the H_0 in the Population	
	True H_0	False H_0
Reject	Type I error	Correct
Fail to Reject	Correct	Type II error

p Value

After alpha is set, researchers collect data on a sample drawn at random from a population(s) for which they will make inferences. It is important to remember that H_0 is set up before data collection. Using data from this sample, the statistic of interest is calculated. Decisions about rejecting H_0 are based upon the likelihood of the observed difference between the sample statistic and

the hypothesized population parameter in a population where H_0 is true. Therefore, the next step is finding the probability of getting the observed difference or a more extreme one on a random sample from a population where H_0 is correct. This probability is called *p* value or $p_{\text{calculated}}$. If the *p* value is less than the alpha level, then H_0 is rejected. The decision to reject H_0 is called a *statistically significant* result. If the *p* value is greater than the alpha level, then H_0 is not rejected, and this decision is referred to as a *statistically nonsignificant* result.

The *p* value, like alpha and all other probabilities, ranges between 0 and 1 and is calculated using sampling distributions. Before explaining *p* value calculations, it is important to understand test statistics.

Test Statistic

After the statistic of interest is calculated using data from a sample, researchers calculate how much the observed statistic in the sample differs from the population parameter stated in H_0 . In any case, researchers would not expect to obtain the same value hypothesized for the population parameter from a random sample because sample statistics will vary around the population parameters. A test statistic quantifies the difference between the sample statistic and the hypothesized population parameter and is a standard score. If the probability of obtaining the observed test statistic or a more extreme one in a population where H_0 is true (i.e., *p* value) is less than the level of significance, then H_0 is rejected. If the *p* value is larger than the alpha, H_0 is not rejected.

Test statistics are calculated using sampling distributions of the sample statistics. Test statistics differ based on the sampling distributions used. The most common test statistics are z , t , F , and χ^2 . Because there is not a unique test statistic used for every H_0 test, rather than the test statistic itself, a probability statement regarding the test statistic (i.e., *p* value) is used to make the decision about H_0 . The *p* value provides a more global language to determine if the statistic differs substantively enough from the hypothesized population parameter to reject H_0 .

To obtain the probability of any test statistics, that particular test statistic's sampling distribution is used. The test statistic sampling distribution is different from the aforementioned sampling distribution, which was the sampling distribution of the statistic of interest. Sampling distributions of test statistics are commonly available in statistics books, on the Internet, or as a function in software. As an example, if the calculated test statistic is a *t*-statistic, the sampling distribution for the *t*-statistic is used to calculate the probability of the observed *t*-statistic.

Example

A heuristic example is used to illustrate *p*-value calculation. Although the sampling distribution and the test statistic will differ, steps used in this example for *p* value calculation can be generalized to other hypothesis testing situations. This example, which compares male and female students' mathematics anxiety levels, is provided to illuminate processes underlying *p* value calculations, so some hypothesis testing details will not be explained or elaborated. Before data collection, as the first step, H_0 and H_a were stated as follows:

H_0 : The population means are the same.

H_a : The population means are not the same.

Second, $\alpha = .05$, in other words, it is decided that 5% probability is an acceptable probability of committing a Type I error. Then, researchers collect data on randomly sampled 40 female and 40 male students. In these samples, the mean mathematics anxiety level for females and males was 200 and 180, respectively. Although the means are not the same in the samples, it cannot be directly concluded that this would also be the case in the population. Because of sampling fluctuation, statistics from random samples will vary around population parameters. Therefore, the probability of obtaining such a difference or a more extreme one in a population where H_0 is true will be obtained.

The third step involves test statistic computation. As mentioned before, test statistics are calculated using sampling distributions of the statistics of interest that are derived mathematically assuming H_0 is true in the population. In this example, the statistic of interest is the mean difference; therefore, the test statistic will be computed using the sampling distribution of mean differences derived assuming the mean difference in the populations is 0. A general formula that can be used in many test statistic calculations is

$$\text{Test statistic} = \frac{\text{Sample statistic} - \text{Hypothesized parameter}}{\text{Standard error of the statistics}}.$$

For this example, assume the standard error of the mean differences is 9 and the test statistic to be computed is a *t*-statistic.

$$t = \frac{(200 - 180) - 0}{9} = 2.2$$

Thus, a mean difference of 20 in the sample is 2.2 standard deviations away from the hypothesized population mean difference, which is 0.

The last step is finding the *p* value, which is the probability of obtaining a *t*-statistic of 2.2 or greater in a population where H_0 is true. Because in this example a two-sided H_a is used, the probability of both $t \leq 2.2$ and $t \geq 2.2$ are needed. To obtain *p* values, a *t*-statistic sampling distribution is used. Using a commonly available *t*-statistic sampling distribution, the probability of $t \leq 2.2$ is approximately .017. Because *t*-distributions are symmetrical, the probability of $t \geq 2.2$ will be approximately .017 also. Therefore, the probability of $t \leq 2.2$ or $t \geq 2.2$ (i.e., *p* value) is around $.017 + .017 = .034$, which is smaller than the alpha value of .05. Because the *p* value is smaller than the alpha, the decision about H_0 is to reject. If alpha was set at .01 instead of .05, then the decision would be to not reject because the *p* value is larger than .01.

Careful Use of *p* Values

Quantitative results are often misinterpreted because the purpose of hypothesis testing in an applied setting can be complex. Partial understandings of hypothesis testing can result in systemic issues that can negatively affect the quality of research reports. For quality research reports, it is important to understand hypothesis testing and *p* values and use them thoughtfully. Therefore, a few comments are provided for the careful use of *p* values.

1. *P* values are substantively affected by sample sizes. When a large sample size is obtained, even very small differences or effects become statistically significant. Therefore, it is fundamental that researchers provide an estimate of practical significance (i.e., effect size) when reporting *p* values.

For illustration, think of two experiments each comparing two groups' means. Experiment 1 consists of two groups (Groups 1 and 2) with 10 members each. The means for Group 1 and Group 2 are 55 and 56, respectively. Experiment 2 also consists of two groups (Groups 3 and 4) but this time with 110 members each. The mean for Group 3 is the same as Group 1, 55, and the mean for Group 4 is the same as for Group 2, 56 (see Table 2). The question in both experiments is, "Are the two means statistically significantly different with $\alpha = .05$?" In Experiment 1, the $p_{\text{calculated}} = .571$, so the means are *not* statistically significantly different, but in Experiment 2, the $p_{\text{calculated}} = .043$, so the means *are* statistically significantly different, although the difference in the means in both experiments is exactly 1 point (see Table 2). This leads to the question, "Which decision is correct?" To examine this phenomenon, one should consider how important the 1-point difference is in both

Table 2 Descriptive Statistics

	Group	Mean	N	SD
Experiment 1	1	55.0	10	5.3
	2	56.0	10	6.7
Experiment 2	3	55.0	110	5.3
	4	56.0	110	6.7

experiments. For this, effect size estimates need to be calculated. This exemplifies that using a large-enough sample size will result in statistically significant results even when effects are inappreciably small.

2. Another implication of *p* value's sensitivity to sample size is that sometimes, statistical significance cannot be obtained because of the small sample size, although the effect might be present in the population. Therefore, as researchers plan their studies, they are encouraged to do a power analysis to determine the appropriate sample size to improve the probability of correctly rejecting H_0 .
3. Researchers commonly report the *p* value to be smaller or larger than alpha or mention that results are statistically significant rather than reporting exact *p* values. However, there is a difference between obtaining statistical significance with a *p* value that is slightly smaller than alpha as compared to when the *p* value is substantively smaller than alpha. The smaller the *p* value, the greater the evidence in favor of H_a . With commonly available online *p*-value calculators and spreadsheet functions, researchers can easily obtain exact *p* values and report them in research reports.

PAIRWISE COMPARISONS

Pairwise comparisons are methods for analyzing multiple population means in pairs to determine whether they are significantly different from one another. This entry explores the concept of pairwise comparisons, various approaches, and key considerations when performing such comparisons.

Concept

Because population parameters (e.g., population mean) are unknown, practitioners collect samples for the purpose of making statistical inference regarding those parameters. As an example, many different statistical methods have been developed for determining if there exists a difference between population means. Perhaps most well-known is Student's t test, which is typically used for inferring from two samples if there exists a difference between the corresponding population means (or, in the case of only one sample, determining if the population mean differs from some fixed constant). As an example, the researcher might be interested in performing a hypothesis test to determine if a particular reading improvement program among children is more effective than the traditional approach in a particular school district. The researcher might draw a sample of children to act as the control group and a similar sample to act as the treatment group. Gauging the effectiveness of the intervention by some measurement tool (e.g., words read per minute or reading comprehension), the researcher might implement a t test to determine if there exists a significant difference between the control and the treatment group means.

In the case, however, that there are more than two means to be compared, the t test becomes less useful. Consider a similar situation in which the researcher wishes to determine if there exists a difference between the effectiveness of several intervention programs. For example, the researcher might want to compare the effectiveness of several different programs that are implanted in each of, say, five school districts in a particular city. The researcher could, of course, simply perform multiple t tests, comparing each of the intervention programs with all of the others. There are at least two critical problems with this approach.

The first is that the number of t tests that are required to be performed dramatically increases as the number of treatment groups increases. In the case of five treatment levels and a single factor, there are only

$\binom{5}{2} = 10$ different t tests that would need to be

performed. In the case, though, that there are multiple factors with multiple treatment levels, this number quickly becomes large. With the increase in computing power, however, this obstacle is not as meaningful as it has been in the past.

The second difficulty is more substantive. The second difficulty with performing multiple t tests to compare several means is that it greatly increases the false alarm rate (i.e., the probability of making a Type I error, which is rejecting the null hypothesis when it is, in fact, true). In the above example, suppose the level of significance is $\alpha = .05$, then the probability of making a Type I error is .05, and the probability of not making a Type I error is .95. Performing 10 t tests, however, each with $\alpha = .05$, causes the probability of committing at least one Type I error to increase to $1 - .95^{10} = 0.4013$. That is, simply using t tests to determine if there exists a difference between any of five population means, each with significance .05, results in around a 40% chance of committing a Type I error.

To alleviate this difficulty, practitioners use global tests of hypotheses. Techniques like analysis of variance (ANOVA) and multiple regression, for example, rely on the F test, a global test, which tests the null hypothesis that all of the group means are equal against the alternative hypothesis that at least one of the group means is different from the others. By specifying the hypotheses in this way, the overall or experimental Type I error rate can be maintained because only one test is actually performed. The drawback is that the alternative hypothesis is much more vague. If the global test leads the researcher to reject the null hypothesis, the conclusion drawn is that the means are not all equal. The test gives no information as to which of the means might be different from which of the others. For example, all of the group means might be different from one another, or all of the group means might be equal except for one. Rejection of the null hypothesis in a global test of hypotheses might take place in either of these circumstances and would not allow the researcher to determine which is the case.

Once the determination has been made that the group means are not all equal (i.e., the null hypothesis in the global test has been rejected), the practitioner may use pairwise comparisons to determine which of the means are significantly different from one another. Stated in terms of hypotheses, if there are k comparisons to be done, then there are k sets of hypotheses of the form $H_0 : \mu_i = \mu_j$ and $H_1 : \mu_i \neq \mu_j$ for all $i \neq j$, $1 \leq i, j \leq a$ where j is the number of treatment groups in the study.

From a notational perspective, suppose that some experiment resulted in four sample means that, when sorted from least to greatest, are denoted by $\bar{x}_1, \bar{x}_2, \bar{x}_3,$

and $\bar{x}_4$ and with corresponding population means denoted μ_1, μ_2, μ_3 , and μ_4 , respectively. Suppose further that some pairwise comparison procedure suggests that μ_1 and μ_2 are not statistically different from one another but that they are statistically different from μ_3 and μ_4 , which, in turn, are not found to be statistically different from each other. Typically, this is denoted as $\underline{\mu_1 \mu_2} \mu_3 \mu_4$, where the means that those that share an underline are not found to be statistically different from one another by the pairwise comparison procedure.

At the heart of each of these procedures is the desire to avoid the problem of increased experiment-wide Type I error rate described above when performing multiple tests. That is, in determining which of the group means are different from one another, the practitioner would like to be able to maintain an overall, experiment-wide Type I error rate of α ; simply performing multiple t tests of size α maintains only a per-statement or pairwise error rate of α , and the overall error rate increases as the number of tests performed increases.

Approaches

One of the very common approaches to pairwise comparisons is to apply a Bonferroni adjustment to the individual comparisons in order to preserve the experiment-wide Type I error rate. The probability of making a Type I error in the i th comparison is denoted as α_i and the experiment-wide error rate as simply α . The Bonferroni inequality (also known as Boole's inequality) states that

$$\alpha \leq \sum_{i=1}^k \alpha_i,$$

where k is the number of pairwise tests to be performed. If the practitioner (very reasonably) uses the same significance level for each pairwise comparison, then we have $\alpha \leq k\alpha_i$. In other words, the practitioner can guarantee that the overall Type I error rate is less than or equal to α by setting the pairwise significance level to α/k , where equality is achieved in the case of independence. Hence, by reducing the significance level of each of the pairwise comparisons, the researcher can control the experiment-wide error rate. However, the Bonferroni adjustment has been shown to be a very conservative approach that fails to allow the researcher to detect important differences between the means (i.e., the power is diminished by an overly conservative approach).

Fisher's least significant difference (LSD) procedure for pairwise comparisons was proposed by Ronald A.

Fisher in 1935 and is among the oldest modern methods for pairwise comparisons. Fisher, who was the first to define and use the term *variance* and who is widely credited with having invented ANOVA, devised the LSD test to solve this problem as it relates to analysis of variance. Fisher's test uses a two-stage approach. First, the global test of hypothesis is considered. If there is not enough evidence to suggest that any of the treatment means are different in the global test, then the decision in the pairwise tests is made in favor of the null hypothesis. If the global test leads to rejection of the null hypothesis, then the practitioner essentially performs k t tests of size α to determine which means are different.

The reader may object that because no correction has been made to the significance level of the individual tests, an increasing experiment-wide Type I error rate will be encountered. Such an observation is correct. Fisher's LSD test does not control the experiment-wide Type I error rate. However, because multiple comparisons are performed only after rejecting the null hypothesis in the first stage, the increase in the Type I error rate is not as pronounced. Despite not controlling the experiment-wide Type I error rate, its simple and intuitive approach has helped it endure.

Tukey's test, also known as the Studentized range test or the honestly significant difference (HSD) test, does control the experiment-wide error rate. This procedure was originally developed for pairwise comparisons only when sample sizes among treatment groups are equal, but it was later adapted to handle treatment groups of unequal sizes. This version of the test, for the unbalanced case, is also known as the Tukey-Kramer procedure. In the balanced case, two population means are considered to be significantly different if the absolute value of the difference of the corresponding sample means is greater than

$$T_a = q_a(p, f) \sqrt{\frac{MSE}{n}},$$

where p is the number of sample means in the study, f is the degrees of freedom used in calculating mean square error (MSE), n is the number of observations in each treatment group, and $q_a(p, f)$ is the $100(1 - \alpha)^{\text{th}}$ percentile of the distribution of the Studentized range statistic,

$$q = \frac{\bar{x}_{\max} - \bar{x}_{\min}}{\sqrt{MSE/n}},$$

where $\bar{x}_{\max}$ and $\bar{x}_{\min}$ refer to the largest and smallest sample means in the sample, respectively.

The naming of Tukey's HSD test communicates that Tukey's test is more conservative than Fisher's LSD test.

This is because Tukey's test controls the overall error rate. For this reason, it is often preferred to Fisher's test.

These three procedures are, by far, the most common for performing general pairwise comparisons. A few other, more specialized techniques, however, bear mentioning. First, Dunnett's multiple comparisons with control (MCC) test, as its name suggests, is used when comparing means against a control. Similarly, Hsu's multiple comparisons with best (MCB) test is used for comparing the other groups with the best among those tested. Because both of these tests control the overall Type I error rate, by reducing the number of comparisons being performed, they increase the power of each of the pairwise tests.

Because the more comparisons made by the practitioner, the smaller the size of the individual tests must be in order to preserve the experiment-wide error rate, one approach is to reduce the number of tests to be made. Dunnett first proposed the test that bears his name, Dunnett's MCC test, in 1955 for the purpose of performing pairwise comparisons when the practitioner is interested only in comparing each treatment group with a control group. If, for example, the researcher were comparing various new training programs with what is currently being used, Dunnett's test would be useful in determining if any of those tests outperform the current standard. The procedure for Dunnett's test is a modification of the t test and generally requires a computer to perform because the table of constants required is not readily available, as it depends on the number of comparisons to be made, the sample sizes of treatment and control groups, and the experiment-wide error rate, and is therefore quite lengthy.

Hsu's MCB test, like Dunnett's test, reduces the number of tests being performed, but instead of comparing treatment groups against a control, groups are compared against the best (or worst in the current sample). As an example, suppose a health agency is attempting to determine which community health program is the most effective at preventing smoking among adolescents. The researcher would undoubtedly like to know the best of the available approaches. If it is the case, however, that the treatment group with the greatest effectiveness is not statistically different from the group with the second highest effectiveness (or even the third highest), then the planning and budgeting offices of the community health organization can understand their options better. Perhaps the test with the highest effectiveness has higher funding requirements, but the second best test is cheaper. A pairwise comparison procedure that can show that its effectiveness is not statistically different from that of the first would be of great interest. In such a case, Hsu's test is called for.

Hsu's test is largely based on Dunnett's MCC test. In fact, they both rely on the same constant and therefore use the same tables of values. The results are also interpreted in similar ways. Whereas Dunnett's MCC identifies significant differences between treatment groups and the control, Hsu's test identifies significant differences between treatment groups and the best, where the definition of best depends on the context of the problem. In the event that high values indicate what is best, the difference of interest is $\mu_i - \max_{j \neq i} \mu_j$. Conversely, where low values indicate what is best, the difference of interest is $\mu_i - \min_{j \neq i} \mu_j$, $i = 1 \dots k$, where k is the number of treatment effects. For simplicity, the example taken will be the former. In this case, a positive difference indicates that the i th mean is larger than all of the others, and a negative difference indicates that the i th mean is not larger than the others. This description is known as the unconstrained approach because the endpoints of the confidence intervals constructed in this approach are not artificially constrained by the practitioner.

Hsu's test, however, is often used to construct *constrained* confidence intervals in which the interval is forced to contain zero. Often, the practitioner is not interested in how much worse the nonoptimum solutions are from the best. Constrained confidence intervals may be used when this is the case. By forcing the interval to contain zero, this test achieves sharper inference.

Many more pairwise comparison procedures have been developed, but they are, in large part, merely variants of those that have been described above. One approach that differs from the above-mentioned approaches is the Waller-Duncan Test. This test implements a Bayesian framework and determines pairwise differences by minimizing the Bayes risk rather than explicitly controlling the experiment-wide Type I error rate. It allows the practitioner to specify a constant, k . This constant is used to make it more (or less) difficult to decide in favor of (or against) the null hypothesis, depending on the potential cost of making the wrong decision (i.e., committing a Type I or Type II error).

Key Considerations

Three key considerations are important when performing pairwise comparisons: First, pairwise comparisons should be performed only after the null hypothesis in the global test of hypotheses has been rejected. Failing to reject this global hypothesis should also be considered a failure to find any of the pairwise comparisons significant. Performing repeated tests in a (frantic) search for significance will, no doubt, inflate the probability of making a Type I error. Second, care should be

paid to the experiment-wide Type I error rate because of the effect of performing multiple tests. Even when using Fisher's test, which does not control the experiment-wide Type I error rate, the practitioner can apply a Bonferroni adjustment to do so. Finally, the quantity of tests can be reduced (thereby increasing the power of the multiple comparisons) by making only comparisons of interest. This is typically done using tests like Dunnett's MCC or Hsu's MCB test but can also be accomplished simply by making fewer comparisons with Fisher's LSD test and adjusting α accordingly.

PANEL DESIGN

A panel design is used when researchers sample a group, or panel, of participants and then measure some variable or variables of interest at more than one point in time from this sample. Ordinarily, the same people who are measured at Time 1 are measured at Time 2, and so on. The successive measures are commonly referred to as *waves*. For example, a three-wave panel study would measure the same sample of participants on three separate occasions. The amount of time in between measurements is known as the *interwave interval*. The use of multiple measures on the same variable(s) over time allows for an assessment of longitudinal changes or stability on the variables of interest.

Perhaps the simplest and most common version of the panel design is the two-wave, two-variable panel, or *cross-lagged panel design*. In this design, two variables (X and Y) are measured at two discrete points in time from the same sample of participants. The procedure allows the researcher to test a series of different associations depicted in Figure 1.

The horizontal paths in the cross-lagged panel model represent *stability coefficients*. These values indicate how stable the X or Y variables are over time. If analyzed with regression, the larger these regression coefficients are, the greater the stability of the X or Y constructs over the course of the interwave interval. The diagonal paths are of particular interest as they are often compared to determine if $X_1 \rightarrow Y_2$ is greater or less than $Y_1 \rightarrow X_2$. This comparison often forms the basis for making causal inferences about whether X causes Y , Y causes X , or perhaps some combination of the two. Although cross-lagged panel designs are very common in the literature, there is a considerable controversy about their actual utility for testing causal inferences. This is because a valid causal analysis based on a cross-lagged panel design involves the absence of measurement error, correct specification of the causal lag between T1 and T2, and the assumption that there is no third variable, Z , that could exert a causal impact on X and Y . Rarely, if ever, are all of these assumptions met.

Despite its limitations, the cross-lagged panel study illustrates several key benefits of panel designs more generally. First and foremost, one of the fundamental prerequisites for establishing that X has a causal effect on Y is the demonstration that X occurs before Y . For

Figure 1 Basic Structure of Cross-Lagged Panel Design

example, if smoking is assumed to cause lung cancer, it is important to be able to demonstrate that people first smoke while otherwise free of cancer, and then lung cancer appears at a later point in time. Merely demonstrating that *X* precedes *Y* in a longitudinal panel study does not prove that *X* causes *Y*, but it satisfies this vital criterion, among several others, for establishing a causal relation. Another important quality of panel designs is that they do not confound interindividual growth with interindividual differences in intraindividual growth, the way that cross-sectional studies do. Because the same people are measured at multiple points in time, it is possible to statistically model changes within the same person over time, differences between people, and interindividual differences in the rate and direction of change over time.

The remainder of this entry addresses important design considerations for studies using panel designs, variants on the prospective panel design, and special problems associated with panel designs.

Panel Study Design Considerations

There are several important research design considerations that must be considered when planning a study with a panel design. One potential problem with interpreting the results of a two-wave panel study is *regression toward the mean*. Over time, extreme scores on any variable have a natural tendency to become less extreme. This statistical artifact has the potential to obscure meaningful longitudinal associations, or lack thereof, between variables in the study. Concerns about regression toward the mean can be alleviated if more than two waves of measurement are taken. For this reason, it is generally advisable to implement three or more waves of measurement in any panel study.

Another important design consideration is proper specification of the *causal lag*. Quite simply, this is a question of how long it takes the effect of *X* to appear on *Y*. In other words, how fast will *Y* change as a function of *X*? The answer to this question has major implications for selecting the appropriate interwave interval. Misspecification of this interval can invalidate the results of a panel study. Assume, for example, that a researcher is interested in testing the effectiveness of a new exercise program on people's weight. An exercise physiologist determines that the initial effect of the program should become evident in approximately 2–3 weeks. If a researcher designs a test of this program's effectiveness with a three-wave panel study that has a 5-day interwave interval, it is likely that the effectiveness of the program will be missed all together. This is because the overall window of observation is too short to allow for the effect of the exercise program to show

up on participants' weight. An interwave interval that is too long can be equally deleterious to testing causal inferences. Assume that a researcher wants to study the effects of losing a family member on people's level of psychological distress. In order to allow for a reasonable probability of observing the event of interest, a 15-year panel study is designed with measures every five years. It is entirely possible that psychological distress might shoot up shortly after the death of a family member, but the designer of this hypothetical study would miss that entirely because the person's psychological distress might return back down to normal levels by the time of the next wave of measurement, because the observations were spaced too far apart. For these reasons, it is vital that those who conduct panel studies have a clear understanding about the causal lag, or time ordering, between the variables of interest and use appropriate interwave intervals that allow for detection of these causal effects. As a general rule, the time lag between cause and effect should be shorter than the interwave interval. Ideally, the timing of observations will be dictated more by a theory of temporal change on the variable(s) of interest rather than logistics.

Related to specification of the causal lag is selection of the *number of waves*. Because of regression toward the mean, two-wave designs are generally less than ideal. However, it is not always clear whether there should be 3, 4, 5, or even 20 waves of measurement. Ordinarily, a higher number of waves is indicated when (a) the causal lag is relatively brief and (b) the probability of the causal event (*X*) occurring or causal variable (*X*) fluctuating that will ultimately influence the dependent variable (*Y*) is relatively low. The use of a larger number of waves will increase the likelihood that the researcher will capture or observe this causal process while the study is ongoing.

Variants on the Prospective Panel Design

An alternative to the prospective panel design is the *retrospective panel design*. In the retrospective panel design, data are collected retrospectively, with respondents providing information on a state of affairs at a point in time prior to the actual data collection. One attractive element of retrospective panel designs is the ability to collect what is essentially longitudinal data at a single point in time. For example, a researcher might be interested in how seat belt usage has changed as a function of laws and manufacturing trends in the auto industry. Perhaps the researcher wants to study seat belt use in 1975 prior to seatbelt legislation; in 1990, when automatic seatbelts started to become standard equipment in many cars; and in 1995, when airbags started to appear in most vehicles. One way to study this would be to obtain a sample of

older adults and ask them to estimate what percent of the time they wore seatbelts during these various years. In effect, the researcher could obtain three waves of data, covering a 20-year period, from a single data collection session. In theory, there should be no attrition as all participants sampled for the study could provide data for all prior points in time.

However, this example also illustrates two important problems with retrospective panel designs. The first and most obvious problem stems from problems associated with recall. Memory for how often one wore seatbelts more than 30 years ago might be vague at best. Memory failure can produce both false positive (recalling use of seatbelts when the respondent did not actually use them) and false negative (failing to recall the use of seatbelts during a period in which they were actually used) recall errors. Another, less obvious problem with retrospective panel designs is censorship associated with survival. Assuming that those who never or rarely wear seatbelts are more likely to die in an auto accident, a sample of adults able to report on 30 years of seatbelt use will be biased toward those who are more likely to wear seatbelts. Those who used seatbelts less frequently are less likely to have survived over the interval of observations and are therefore less likely to appear in the study's sample. The retrospective panel design described in this example is a *follow-back* panel design whereby cases are sampled in the present and data from earlier points in time are generated by the participants. In the *catch-up* panel, a cross-sectional sample is secured on the basis of data from an archival source (e.g., men who registered for the selective service in 1980), and those cases are located at the present time to generate data for the present, and perhaps for the period in between the index event and the present.

Another variant of the prospective panel design is known as a *rotating panel design*. In this design, data are collected repeatedly from a sample of cases. However, over subsequent waves, some cases are dropped and replaced with new cases. One of the desirable qualities of the rotating panel design is minimization of problems associated with attrition, measurement, and fatigue. For example, assume that an economist is interested in studying the association between the market value of various precious metals and the welfare of residents in mining communities. Because of the volatile nature of the precious metals market, it is desirable to conduct assessments at least once every 6 months. However, over a period of many years, repeated measurements from the same participants could become a burden, plus some people are likely to drop out of the study. These effects can be counteracted by recruiting a new, but comparable, sample to replace those who are dropped from the study after some predetermined time

frame (e.g., 2 years). So long as the cause → effect time lag is shorter than the period for which the same set of participants remains in the study—in this case, 2 years—causal inferences can be evaluated with such data. This is because short-term change on the individual level can be evaluated with a subset of the data. At the same time, long-term change at the group level is possible due to the overall homogeneity of the sample (e.g., all residents of mining communities).

Closely related to the revolving panel design is the *accelerated longitudinal design* first described by Richard Bell in 1953. In the accelerated longitudinal design, multiple panels are recruited and followed over a specified time interval. These panels have the quality of being uniformly staggered on key developmental stages. For example, assume that a linguist wants to study the depth and breadth of language acquisition between ages 3 and 15. However, the linguist does not have 12 years to conduct the investigation. In the accelerated longitudinal design, the linguist could recruit four panels of children who are 3, 5, 7, and 9 years old and follow them all for a period of 3 years. In so doing, the researcher could collect 12 years' worth of developmental data in a period of only 3 years. One might wonder, why not collect data on 3-, 6-, and 9-year-olds for 3 years? This is because ideally there should be some overlap between the cohorts on the developmental variable on which they are staggered, in this case, age. In this example, data on language acquisition during the fifth year of life would be available from both Panel 1 and Panel 2, albeit at different times during the course of the study. This ability to link the panels plays an important role in the causal inference process. A major advantage of accelerated longitudinal designs is the ability to study aging effects independent of period effects. Over a 12-year period, societal changes in instructional technology, computers, and so on might account for greater depth and breadth of language acquisition. By accelerating the collection of 12 years' worth of data to only 3 years, these period effects are minimized. A serious drawback of accelerated longitudinal designs is that intra-individual changes can be studied only over much shorter intervals than what is represented in the totality of the design. In cases where there are longer-term causal effects, this can pose a very serious problem for testing causal inferences. Accelerated longitudinal designs also assume that a single growth trajectory is sufficient for describing all cohorts or panels, and this assumption might not be valid in some cases.

Special Problems With Panel Designs

Notwithstanding their numerous benefits, panel studies have a series of special problems that must be taken into consideration. First, panel studies have unique

problems associated with *attrition*, which is sometimes known as *mortality*. Attrition occurs when people who started the study at Time 1 eventually drop out before the final wave of measurement. Obviously, this is largely a problem with prospective panel designs, in contrast to retrospective panel designs. The longer the study and the more waves of assessment, the greater the likelihood of experiencing significant attrition. Attrition can introduce systematic bias into the data set generated by a panel study. For example, a researcher might want to test the effectiveness and perseverance of a drug rehabilitation program by following a sample of people who have recently completed the rehabilitation program and assessing their substance use and well-being every year for 10 years. At the end of the study, the rehabilitation program might appear to have been a resounding success. However, this could potentially be an artifact of attrition. What if the reality was that 35% of the cases relapsed and dropped out of the study due to poor health, hospitalization, incarceration, or even death from overdose? Only the well-functioning cases would be left in the study. This could easily lead the researcher to the wrong conclusion about the program because perseverance in the study is confounded with well-being.

In very long-term panel studies that sometimes take place over decades, the state of the art for *measurement* of the study's variables might change dramatically. Indeed, the very conceptual definition of the study's constructs (e.g., domestic violence, ideal body weight, mental illness) might change over time. The researcher is thus faced with the dilemma of using the old and outdated definition and measure that were used at Time 1, or to adopt the new, state-of-the-art measure at a later wave of assessment, therefore assuming the risk that the two different measures might not be comparable. In such cases, it might be unclear if a key variable changed meaningfully over time, or if the two different measures just produced different results.

Testing effects can occur any time participants are subjected to repeated assessments of the same or a similar set of variables over time. If an epidemiologist wanted to study the effects of smoking and drinking on the risk for developing certain health problems, participants in the study might adjust their levels of smoking and drinking merely because they know that they will be asked questions about these behaviors in the near future and are thus more consciously aware of them and perhaps their negative potential consequences.

In retrospective panel designs, *selection* can be a substantial problem. A retrospective study of smoking

and heart disease will left-censor cases of heavy smokers who had heart disease and did not survive up to the index date when the sample was selected. In effect, 100% of the sample will appear to have survived in the retrospective panel study, when in real life, this would not be the case. Even prospective panel studies might encounter problems with selection. Informed consent requires that participants are fully informed of the nature of an investigation prior to volunteering for it. Prospective panel studies that take place over very long periods of time with numerous waves of data collection might filter out certain people who do not want to assume that burden.

A final problem with any panel design aimed at testing causal inferences is the *proxy variable problem*. This happens when it is assumed from the analysis of the panel study data that *X* causes *Y*. However, in reality, *X* might merely be a proxy for some other variable, *W*, that is the true cause of *Y*. Longitudinal panel studies that tested the effects of parental divorce on children's well-being revealed that the occurrence of parental divorce is predictive of subsequent decreases, albeit small in magnitude, of children's psychological well-being. However, more careful analyses revealed that parental divorce was a proxy for such other variables as (a) parental conflict, (b) parental absence, and (c) lower family socioeconomic status, all of which can exert a causal effect on children's psychological well-being independent of parental divorce. The proxy variable problem is yet another illustration of why it is important to have a strong theory that specifies how, why, and under what conditions the cause-and-effect variables are linked.

PARADIGM

Originally, *paradigm* was a word referring to an accepted model or pattern. In *The Structure of Scientific Revolutions*, Thomas Kuhn gave this word a new meaning, using it to represent the set of practices that constitutes the core of a scientific discipline and serves as a model to show how a scientific community should conduct its research.

In *Structure*, Kuhn defined a paradigm simply as a group of exemplary problem solutions universally accepted by the members of a scientific community. According to Kuhn, what constitutes a paradigm is not abstract theories but rather concrete applications of the theories for solutions of typical problems. For example, the paradigm of Newtonian mechanics does not consist of Newton's equations of motion but rather exemplary applications of these equations in solving such standard problems as free fall, simple pendulum, and inclined planes. By forming analogies to these exemplary problem solutions, scientists conduct their research in a coherent way and establish a consensual core for the discipline. Initially, Kuhn did not think that paradigms exist in social sciences, because social scientists usually belong to competing schools and they are unable to reach universal consensus on what a common practice should be in their field.

Kuhn's notion of paradigm evolved after the publication of *Structure*. One development was that Kuhn gradually turned "paradigm" into a more inclusive concept. In the postscript of *Structure*, Kuhn introduced the notion of "disciplinary matrix" to replace the paradigm concept in the broad sense. The term *matrix* suggests that it is composed of various elements. In addition to exemplary problem solutions, a disciplinary matrix also includes the following three components:

1. *Symbolic generalizations*. These are formal or formalizable expressions used by a scientific community as universal laws or equations, such as the symbolic form $f = ma$ defined by the second principle of Newtonian mechanics.
2. *Models*. These include heuristic analogies that help scientists to analyze and understand certain phenomena, such as using a hydrodynamic system as an analogy of an electric circuit. These also include metaphysical analogies used to justify certain ontological assumptions, such as using a group of tiny elastic billiard balls in random motion to illustrate the nature of gas.
3. *Values*. These are convictions shared by a scientific community, such as the belief in the significance of accuracy or simplicity.

Another development was that Kuhn eventually abandoned universal acceptance as the requirement for paradigms. Kuhn realized that scientific schools competing with each other may also have their own internal consensus, and he agreed to label the consensus of a school a paradigm. After this revision, the concept of paradigm becomes applicable in social sciences.

Paradigm Shifts

Kuhn called research conducted within the framework defined by a paradigm *normal science*. Routine research activities during normal science include gathering facts, matching facts with theories, and articulating theories. The aim of research in this stage is not to produce major novelties, but to solve puzzles. Scientists are confident that the paradigm can offer them all the necessary tools to solve puzzles, and they usually blame themselves rather than the paradigm when they encounter anomalies, that is, puzzles that have resisted solutions.

If some anomalies are persistent or challenge the fundamentals of the paradigm, they can eventually erode scientists' faith in the paradigm. The result is a crisis, which is frequently followed by a paradigm shift. A scientific revolution occurs, through which a new paradigm replaces the old one.

The most important contribution that Kuhn made in his study of paradigm shifts is his thesis of incommensurability. Kuhn believed that rival paradigms during a scientific revolution are incommensurable, in the sense that scientists from rival paradigms cannot communicate with each other without loss. In *Structure*, Kuhn uses Gestalt shifts as an analogy to illustrate his incommensurability thesis. According to Kuhn, after a revolution, those who belong to the new paradigm see things in an entirely different way, as if they were wearing glasses with inverting lenses. The Gestalt analogy implies a complete communication breakdown between scientists who belong to rival paradigms.

Kuhn later modified his position. In the postscript of *Structure*, he dropped the Gestalt analogy, abandoning the implied perceptual interpretation of the thesis. He instead developed a metaphor based on language: During scientific revolutions, scientists experience translation difficulties when they discuss terms from a different paradigm, as if they were dealing with a foreign language. Incommensurability is confined to meaning change of concepts and becomes a sort of untranslatability.

In 1983, Kuhn introduced a notion of "local incommensurability" to narrow the scope affected by revolutions. During a scientific revolution, most of the terms function the same way in both paradigms and do not require translation. Meaning change occurs only to a

small subgroup of terms, and problems of translatability or incommensurability are merely a local phenomenon.

Continuing this direction, Kuhn in 1991 further limited the scope of incommensurability by introducing a theory of kinds: Meaning change occurs only to a restricted class of kind terms or taxonomic terms. In this way, Kuhn redraws the picture of scientific revolutions. Because the interconnections among kind terms form a lexical taxonomy, scientific revolutions, which now are limited to the meaning change of kind terms, become taxonomic changes. A scientific revolution produces a new lexical taxonomy in which some kind terms refer to new referents that overlap with those denoted by some old kind terms. Scientists from rival paradigms face incommensurability because they construct different lexical taxonomies and thereby classify the world in different ways.

The Progress of Science

One implication of the incommensurability thesis is that it is impossible to evaluate rival paradigms rationally, because there are no shared evaluation standards between those belonging to rival paradigms. In *Structure*, Kuhn affirmed this relativist position by citing the famous remark from Max Planck: "A new scientific truth does not triumph by convincing its opponents and making them see the light, but rather because its opponents eventually die, and a new generation grows up that is familiar with it" (p. 151).

Kuhn later tried to retreat from this relativist position by developing an analogy between scientific development and biological evolution. In *Structure*, Kuhn already used an analogy to biological evolution to illustrate scientific revolutions. Scientific development is parallel to biological evolution in the sense that both are products of competition and selection. Scientific development is a process driven from behind, not pulled from ahead to achieve a fixed goal. Kuhn further explicated this analogy in 1992, revealing another important similarity: Both scientific development and biological evolution have the same pattern of growth in the form of an evolutionary tree. Whereas proliferation of species is the form of biological evolution, proliferation of specialized disciplines is the key feature of scientific progress. The pattern of knowledge growth is an inexorable growth in the number of distinct disciplines or specialties over the course of human history.

With the analogy to biological evolution, Kuhn proposed an evolutionary epistemology to specify the evaluation standards for scientific development. The key of this new epistemology is to distinguish between evaluation of stable belief and evaluation of

incremental change of belief. When we evaluate the development of two beliefs, it makes no sense to say that one is "truer" than the other, because there is no fixed platform that can supply a base to measure the distance between current beliefs and the true belief. To evaluate the incremental change of belief, one must apply a different criterion, the proliferation of distinct specialties. Thus, although incommensurability may continue to create inconsistent evaluation standards between rival communities, this confusion does not necessarily lead to a total failure of rational comparisons. The evolution of knowledge consists of the proliferation of specialties, the measurement of which is not only practicable but also frequently independent of the theoretical positions of evaluators. A rational evaluation of knowledge development is possible even when people employ different evaluation standards.

PARALLEL FORMS RELIABILITY

Parallel forms reliability (sometimes termed *alternate forms reliability*) is one of the four primary classifications of psychometric reliability, along with test–retest reliability, inter-rater (or inter-scorer, inter-observer) reliability internal consistency reliability. The different categorizations of reliability differ primarily in the different sources of non-trait or non-true score variability, and secondarily in the number of tests and occasions required for reliability estimation. This entry discusses

the construction of parallel forms and the assessment, benefits, and costs of parallel forms reliability.

Construction of Parallel Forms

The creation of parallel forms begins with the generation of a large pool of items representing a single content domain or universe. At minimum, the size of this item pool should be more than twice the desired or planned size of a single test form, but the item pool should also be large enough to establish that the content domain is well represented. Parallel test forms are generated by the selection of two item sets from the single universe or content domain. The nature of this selection procedure can vary considerably in specificity depending on setting, from random selection of items drawn from the homogeneous item pool, to paired selection of items matched on properties such as difficulty. The resulting forms will typically have similar overall means and variances.

A subtle distinction can be drawn between the concept of parallel forms as it is popularly used and the formal psychometric notion of parallel tests. In the context of classical test theory, parallel tests have identical latent true scores, independent errors, and identical error variances. In practice, two forms of a test considered to be parallel do not meet the formal standards of being parallel tests but often approach such standards depending on procedures used in the item assignment process.

Parallel forms represent two distinct item sets drawn from a content domain. Multiple test forms that contain non-distinct sets (i.e., overlapping items) are useful in many situations. In educational settings, multiple test forms can be created by scrambling items, which ideally discourages cheating via the copying of nearby test answers. In this case, the two forms are actually the same form in terms of content, and the appropriate reliability assessment would be test–retest. Identical items may also be placed on two test forms to facilitate a comparison of their characteristics under differing conditions (e.g., near start *vs.* end of test).

Assessment

Parallel forms reliability is assessed by sequentially administering both test forms to the same sample of respondents. The Pearson correlation between scores on the two test forms is the estimate of parallel forms reliability. Although the administration procedures for parallel forms reliability differ from test–retest reliability only in the existence of a second test form, this has important implications for the magnitude of the reliability coefficient. In the estimation of parallel forms

reliability, error variance is composed not only of transient error occurring between Time 1 and Time 2 but also of variance due to differing item content across forms. Thus, test–retest reliability tends to be greater in magnitude than parallel forms reliability. A negligible difference between the two estimates would suggest minimal contribution of varying item content to error variance and strong evidence supporting the use of the forms.

Benefits and Costs

The development of parallel forms affords several advantages in both research and applied settings. Generally speaking, the existence of multiple forms sampled from a given content domain is useful whenever sampling or design issues preclude the use of a single test form. Populations differing in primary spoken language, or who have visual or hearing impairments, can be assessed using specially designed measurement instruments that will yield comparable scores with other populations. Practice effects, or other types of accumulated error that often confound situations where subject progress is being assessed, can be reduced when one or many parallel forms are administered at later time points in the assessment.

These potential advantages do not come without concomitant costs. Investments of time and money can effectively double when generating parallel forms, and the utility of these investments must be weighed against the potential gains from developing a measure of a different content area. In addition to costs involved in the development of the forms themselves, the content domain must be sampled more deeply, likely requiring a broader and more careful delineation of the domain boundaries as well as increased care taken not to oversample subsets that may exist within the domain.

PARAMETERS

Parameters are characteristics of populations—they describe the population. In research design, one is often interested in estimating certain parameters of a defined population or testing hypotheses on them. A clear understanding of the objectives of the study will influence the parameter(s) of importance. Consider the situation of environmental pollution in a certain city or region. Suppose that a measure of environmental pollution is the level of carbon monoxide in the air. A parameter could be the mean level of carbon monoxide per specified unit volume. This entry describes the types and categories of parameters; discusses the use of parameters in probability distributions, estimation, and hypothesis testing; and suggests a focus for future research.

Types of Parameters

In general, parameters are either discrete or continuous. For the example considered previously (mean level of carbon monoxide per unit volume), the parameter is continuous. It can take on an infinite number of values on a continuum scale. On the other hand, consider a binomial distribution, where each person is asked whether he or she prefers a given product or not. In this situation, there are two parameters. The first represents the number of persons selected (n), and the second is the proportion of people who prefer the product (p). The parameter n is discrete, whereas the parameter p is continuous.

Different categories of parameters may define different features associated with the population. Consider, for example, the location parameter—three common ones are mean, median, and mode. The population mean, μ , is a measure of location or central tendency of the elements in the population. It is one of the most widely used parameters of interest in research designs. Typically, when an experiment is conducted based on a design, one is interested in determining if a treatment has any effect on the population mean response. The median could be of interest in applications of

nonparametric tests, where the assumption of normality of the response variable may not hold. The mode is used very infrequently in research design as a parameter.

Another category of parameters is that associated with variability in a population. Examples are the range, standard deviation, variance, and interquartile range. Of these, the standard deviation and variance are widely used. The population standard deviation is usually denoted by σ and the population variance by σ^2 . In a majority of research design problems, even if the population dispersion parameter, σ^2 , is not directly of interest, it does show up indirectly in assumptions pertaining to statistical hypothesis tests on the population means. A common assumption in these tests is that of homogeneity of population variances, which assumes that the variances of the population distributions associated with each treatment are equal.

Probability Distribution Parameters

Parameters that completely specify the probability distribution of a certain random variable are known as probability distribution parameters. The most commonly used one in practice relates to the normal probability distribution, whose density function is given by

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]. \quad (1)$$

The two parameters in Equation 1 are the population mean, μ , and the population standard deviation, σ . Knowledge of these two parameters gives us complete information about the nature of the distribution. Hence, it is of interest to estimate these parameters or test hypotheses on them.

Estimation and Hypothesis Testing on Parameters

In general, point estimation and interval estimation techniques exist. In point estimation, a single number or value is used as an estimate, while in interval estimation, a range or interval is specified, such that the probability of the interval containing the desired parameter is of a desired probability level. Concepts of interval estimation are based on the sampling distribution of the associated estimator.

A common estimator of the parameter population mean, μ , is the sample mean, $\bar{X}$. Through use of the Central Limit Theorem, the sampling distribution of the estimator may be established. Similarly, the sample variance, s^2 , is a common estimator of the population variance, σ^2 , where s^2 is given by

$$s^2 = \sum \frac{(X_i - \bar{X})^2}{(n-1)}, \quad (2)$$

where n represents the number of observations in the sample, X_i represents the i th observation, and $\bar{X}$ represents the sample mean. Note that $\bar{X}$ is obtained from

$$\bar{X} = \frac{(\sum X_i)}{n}. \quad (3)$$

There are two desirable properties of estimators. The first refers to that of unbiasedness, whereby the expected value of the estimator equals the true value of the parameter. The second desirable property is that of minimum variance, which assures us that the estimator does not fluctuate much from sample to sample.

In research designs, a simple hypothesis or a joint hypothesis could be of interest. A simple hypothesis is used when we want to test whether the effect of a treatment achieves a certain mean response. For example, does a certain drug change the mean cholesterol (μ) from a certain level (μ_o)? The null and alternative hypothesis could be stated as

$$H_0 : \mu = \mu_o \quad H_a : \mu \neq \mu_o. \quad (4)$$

Alternatively, if several drugs are being tested on their effect on mean cholesterol levels, it might be of interest to determine if at least one drug has a significantly different effect from the others. The following hypotheses could be stated

$$H_0 : \mu_1 = \mu_2 = \mu_3 = \dots = \mu_p \quad (5)$$

H_a : At least one μ_i is different from the others:

Here, p represents the number of drugs used in the design.

Future Research

Ever since the discovery of the Gaussian (or normal) distribution to describe certain phenomena that exist in nature, parameters have a special place in research designs. Parameters not only describe the properties and characteristics associated with the particular distribution, they assist in making predictions. However, in this process of making predictions, through experimentation, parameter values are usually unknown. Future work should focus on effective and efficient estimation methods.

PARAMETRIC STATISTICS

Parametric statistics are the most common type of inferential statistics. Inferential statistics are calculated with the purpose of generalizing the findings of a sample to the population it represents, and they can be classified as either parametric or nonparametric. Parametric tests make assumptions about the parameters of a population, whereas nonparametric tests do not include such assumptions or include fewer. For instance, parametric tests assume that the sample has been randomly selected from the population it represents and that the distribution of data in the population has a known underlying distribution. The most common distribution assumption is that the distribution is normal. Other distributions include the binomial distribution (logistic regression) and the Poisson distribution (Poisson regression). Additionally, parametric statistics require that the data are measured using an interval or ratio scale, whereas nonparametric statistics use data that are measured with a nominal or ordinal scale. Some frequently used parametric tests that include the assumption of a normal distribution include the following: Student's t test, analysis of variance, Pearson's r correlation, and linear regression. Selection of the correct statistical test is important because if the wrong test is selected, the researcher increases the chances of coming to the wrong conclusion.

This entry first reviews inferential statistics methodologies. Next, it discusses the underlying assumptions for parametric statistics and parametric methods and corrections for assumption violations. Finally, this entry discusses the advantages of parametric statistics.

Inferential Statistics

There are two types of methodologies used in inferential statistics: hypothesis testing and estimation of

population parameters. Each of these methodologies includes parametric and nonparametric tests.

Hypothesis testing uses sample data to test a prediction about a population or the relationship between two or more populations. The predictions are stated as two statistical hypotheses. The null hypothesis, H_0 , states that there is no effect or no difference. The alternative hypothesis, H_a , indicates the presence of an effect or difference. This is usually the hypothesis that the researcher expects to be supported. Within hypothesis testing, it is possible for a researcher to commit two types of errors, Type I and Type II. A Type I error occurs when a true null hypothesis is rejected; that is, the conclusion is made that the alternative hypothesis is true when it is not. The likelihood of committing such an error is specified by the alpha level. For example, the likelihood of committing a Type I error if $\alpha = .05$ is 5%. A Type II error occurs when a false null hypothesis is not rejected; that is, the conclusion is made that an alternative hypothesis is not true when it is. The likelihood of committing such an error is specified by beta, β . This is related to the power of a statistical test. Power refers to the probability that a null hypothesis will be rejected when it is false—in other words, the probability of finding a statistically significant result. Power depends on the significance level (α), the sample size, and the population effect size.

Estimation of population parameters includes point estimation and interval estimation. Point estimation involves estimating the parameter value from the computed sample statistics. It is the “best guess” for an unknown population parameter. Statistics refer to characteristics of an observed sample and are measured using measures of central tendency (i.e., mean, median, mode) and measures of variability (i.e., variance and standard deviation). Parameters refer to characteristics of a population. Interval estimation, the more commonly used, involves using sample data to compute a range of values that includes the unknown population parameter. The confidence interval is the most common form of interval estimation.

An additional measure that is often estimated is the effect size, or magnitude of treatment effect. This value estimates the strength of an apparent relationship by estimating the proportion of variance on the dependent variable that can be attributed to the variance of the independent variable, rather than assigning a significance value.

Assumptions

The term *parametric* was first introduced by Jacob Wolfowitz in 1942 as the opposite of *nonparametric*. He described parametric statistics as those that assume

variables have a known functional form and nonparametric as those where the functional form is unknown. Parametric statistics allow one to use sample statistics to make inferences about a population parameter or parameters. Nonparametric tests, on the other hand, make fewer assumptions about the underlying distribution and therefore do not allow one to make inferences about the population. Assumptions may be thought of as “rules” or “guiding principles” for a particular statistic. For example, in analysis of variance (ANOVA), three assumptions must be met for this parametric test to be used. The first assumption is that the data follow a normal distribution. The second assumption is that the variances between groups are equal. This assumption is referred to as the homogeneity of variance assumption. The final assumption of ANOVA assumes that errors associated with any pair of observations are independent (either within the same group or between groups). This assumption is known as the independence of errors assumption, and the violation of this assumption is typically related to design. It is important to recognize and adhere to the assumptions of the test. Violations of assumptions of parametric tests decrease the reliability of the test statistic. However, many parametric tests are considered robust to certain violations—that is, the Type I error rate is not affected despite departures from assumptions. For example, ANOVA has been shown to be somewhat robust to departures from normality but is less robust to violations of homogeneity of variance.

Distribution

As previously mentioned, the most common assumption of parametric tests is that the population from which the sample is taken has an underlying normal distribution. Knowing the underlying distribution of the variable allows for predictions to be made. That is, with repeated sampling of equal sizes of a particular population, the estimate will be approximately the same. The shape of the normal distribution is such that the closer a score is to the mean, the more frequently it occurs.

Sample

Generally, it is not possible to collect data on an entire population; therefore, sample data are used in order to make inferences to the population. It is important to have a representative sample of a population in order to make generalizations to that population. Ways to ensure a representative sample include random sampling and sampling as large of a sample as is feasible. Having a random sample is an assumption of inferential statistics as it decreases the odds of having a biased sample. Additionally, the larger the sample size, the

more likely it is that the shape of the sampling distribution will approach a normal distribution. This principle is known as the central limit theorem.

Measurement Issues

Another assumption of parametric tests is based on the level of measurement. The level of measurement is a representation of how much information the data are measuring. Parametric tests require that the data include more information and thus require interval- or ratio-scaled data. An interval scale is characterized as having an equal distance between measurements throughout the scale that correspond to equal differences in the quality being measured that can be compared in a meaningful way. Interval scales do not have a true zero. A ratio scale has the same equal and meaningful distances between measurements as the interval scale and does have a true zero. Data that follow a nominal or ordinal scale contain less information and are typically analyzed using nonparametric tests. Some controversy exists in the categorization of measurement levels and their application to the decision of whether it is appropriate to use parametric statistics, particularly in determining whether a particular test is on an interval scale (parametric statistics may be used) or an ordinal scale (nonparametric is preferred).

Parametric Methods

Single Sample

Parametric tests that are concerned with testing a hypothesis about a population mean include the single-sample z test and single-sample t test. Parametric tests for population parameters other than the mean include single-sample chi-square test for population variance, single-sample tests for evaluating population skewness and kurtosis, and the D'Agostino-Pearson test of normality.

Independent Samples

For hypothesis testing about the difference between two independent population means, the t test for independent samples may be used. For multiple groups, one could use single-factor between-subjects analysis of variance (ANOVA), single-factor between-subjects analysis of covariance (ANCOVA), or multivariate analysis of variance (MANOVA).

Dependent Samples

For hypothesis testing about the mean differences between two variables measured in the same sample,

the t test for dependent samples or the z test for two dependent samples may be used. Additionally, if more than two variables are measured in the same sample, a within-subjects ANOVA, ANCOVA, or MANOVA may be used.

Relationships Between Variables

To express a bivariate relationship, a Pearson product-moment correlation coefficient, Pearson's r , may be calculated. Multivariate extensions include the multivariate correlation coefficient, partial correlation coefficient, and semipartial correlation coefficient.

Effect Size Estimates

Parametric effect size estimators are associated with the particular statistical test being utilized and include the Pearson's r correlation, Cohen's d index, Cohen's f index, Hedges' g , Glass's Δ , and omega squared.

Corrections for Assumption Violations

As mentioned, the majority of parametric statistical tests include the assumption of normality. It is important to investigate one's sample data to ensure that this assumption has been met, and if it has not, there are possible ways to correct the violation. Significance testing for skewness and kurtosis can be used to test for normality. Non-normally distributed data can occur for multiple reasons. One reason may be due to data that were entered incorrectly in the data analysis program or the inclusion of incomplete data in the analyses. This problem can be remedied by reviewing the data in the data analysis program and correcting the incorrect value or by adjusting for incomplete data in the analyses.

Handling Outliers

Another possible reason for non-normally distributed data is the presence of outliers. Outliers are extreme values on a variable (univariate outlier) or an extreme combination of values on two or more variables (multivariate outlier). Outliers are problematic as they influence results more than other points, and they tend to be sample specific, thus hurting the generalizability of results across samples and therefore the ability to make inferences to the population. A univariate outlier can be identified by investigating a frequency distribution table and identifying values that meet a particular criterion, such as mean ± 3 standard deviations or median ± 2 interquartile ranges. A multivariate outlier may be identified by examining scatterplots or using Mahalanobis distance. There are two options for dealing with outliers.

If it can be determined that the outlier is not from the intended population, it may be deleted. If it cannot be determined that the outlier is not from the intended population, the outlier may be changed so as to have less impact on the results, such as bringing the outlier to the upper or lower criterion used for identification.

Data Transformation

Another possible solution for dealing with data that violate an assumption of a parametric test is to transform the data so that they fit the assumption more satisfactorily. Data transformations put the data on another scale, which can help with outliers and deviations from normality, linearity, and homoscedasticity. Particular transformations can be more beneficial depending on the types of skew. For example, when the data are positively skewed, a square root transformation can often produce a more normally distributed pattern of data or even equate group variances. For a severe positive skew, logarithm transformation may be useful; for negative skew, reflecting the variable and then using a square root transformation, and for severe negative skew, reflecting the variable and then using a logarithm transformation are useful. After the transformation, it is important to recheck the assumptions. Although data transformation can help, it may also make data interpretation difficult or unclear.

Robust Statistics

Robust statistics may also be of use when one needs to compensate for violated assumptions. For example, Welch's t test is used when the homogeneity of variance assumption is violated and provides a corrected critical value. The term *robust* means that even when an assumption is violated, the Type I error rate will remain within an acceptable range (typically .05). However, when choosing a robust statistic, one should keep in mind that many are considered robust only when a single assumption has been violated, as in the case of Welch's t test.

Finally, increasing the sample size by collecting additional data may also remedy any violations to key assumptions.

Advantages

Over the years, there has been considerable debate over whether to use parametric or nonparametric tests. In general, most researchers agree that when the data are interval or ratio and one has no reason to believe that assumptions have been violated, parametric tests should be employed. However, if one or more assumptions

have been violated, nonparametric methods should be used. It is preferable to use nonparametric tests in these cases, as violations of assumptions of parametric tests decrease the reliability of the test statistic. Additionally, if the sample size is sufficiently large, it is appropriate to use parametric statistics as the larger the sample size, the more normal the sampling distribution. However, some researchers believe that nonparametric tests should be the first choice, as it is often difficult to show that assumptions have not been violated, particularly assumptions of normality.

One advantage of parametric statistics is that they allow one to make generalizations from a sample to a population; this cannot necessarily be said about nonparametric statistics. Another advantage of parametric tests is that they do not require interval- or ratio-scaled data to be transformed into rank data. When interval- or ratio-scaled data are transformed into rank-scaled data, it results in a loss of information about the sample. In practice, many researchers treat variables as continuous and thus use parametric statistical methods, when the underlying trait is thought to be continuous even though the measured scale is actually ordinal. This is particularly true when the number of categories is large, approximately seven or more, and the data meet the other assumptions of the analysis. A third advantage of using parametric tests is that these tests are able to answer more focused research questions. For example, the nonparametric Whitney-Mann-Wilcoxon procedure tests whether distributions are different in some way but does not specify how they differ, whereas the parametric equivalent t test does. Additionally, because nonparametric tests do not include assumptions about the data distribution, they have less information to determine significance. Thus, they are subject to more Type II error. Therefore, if a parametric test is appropriate, it gives one a better chance of finding a significant result.

One practical advantage of parametric tests is the accessibility of statistical software programs for conducting parametric tests. There are numerous software programs readily available for conducting parametric tests, whereas there are very few that produce confidence intervals for nonparametric tests. In addition, the computational formulas for conducting parametric tests are much simpler than those for nonparametric tests.

When choosing whether to use parametric or nonparametric tests, many researchers consider parametric tests to be robust and do not recommend replacing them unless the violations of normality and homogeneity of variance are severe.

There are many advantages to using parametric statistics as opposed to nonparametric statistics. However, deciding which type of inferential statistic (parametric

vs. nonparametric) is most appropriate given the particular situation is a decision that must be considered and justified by the researcher.

PARTIAL CORRELATION

A partial correlation is a measure of the relationship that exists between two variables after the variability in each that is predictable on the basis of a third variable has been removed. A partial correlation, like a conventional Pearson product-moment correlation, can range from -1 to $+1$, but it can be larger or smaller than the regular correlation between the two variables. In fact, a partial correlation is simply a conventional correlation between

two sets of scores. However, the scores involved are not the scores on the original variables but instead are residuals—that is, scores reflecting the portion of the variability in the original variables that could *not* be predicted by a third variable.

As a concrete example, a researcher might be interested in whether depression predisposes individuals to interpret neutral faces as manifesting a negative emotion such as anger or sadness but may want to show that the relationship is not due to the effects of anxiety. That is, anxiety might be confounded with depression and be a plausible rival explanatory variable, in that more depressed individuals might tend to have higher levels of anxiety than less depressed individuals, and it may be known that more anxious individuals tend to interpret emotions in neutral faces negatively. A partial correlation would be directly relevant to the researcher's question and could be used to measure the relationship between depression and a variable assessing the tendency to interpret neutral faces negatively, after one has removed the variability from each of these variables that is predictable on the basis of an individual's level of anxiety.

Partial correlations are convenient and have wide applicability, but they are often misunderstood. There are conceptual and statistical issues that must be kept in mind when working with partial correlations. The formula used in the computation of a partial correlation is first introduced, and then several issues bearing on the interpretation of partial correlations are briefly considered.

Formula for Partial Correlation

The partial correlation, denoted $r_{12.3}$, between a pair of variables (Variables 1 and 2) controlling for a “third” variable (Variable 3) may be readily computed from the pairwise or bivariate correlations among the three variables by using the formula

$$r_{12.3} = \frac{r_{12} - r_{13}r_{23}}{\sqrt{1 - r_{13}^2} \sqrt{1 - r_{23}^2}}.$$

Understanding partial correlations is greatly facilitated by realizing how this formula flows from the definition of a correlation. A correlation may be defined either as the ratio of the covariance between two variables to the product of their standard deviations or as the average product of the individuals' *z* scores or standard scores on the two variables:

$$r_{XY} = \frac{s_{XY}}{s_X s_Y} = \frac{\sum z_X z_Y}{N}.$$

(The final value of r is unaffected by whether N or $N - 1$ is used in the denominators of formulas for the covariance and variances because the sample size terms in the numerator and denominator cancel out. This may be less obvious but is still true in computing r as the average product of z scores, given the standard deviations used to compute the z scores could have been calculated using either N or $N - 1$. N is used on the right in the equation to conform to the typical connotation of computing the “average” product of z scores as implying a division by N , although it should be noted that this implies that the “average” or “standard” deviations also are computed using N rather than $N - 1$.)

As noted, a partial correlation is a correlation between residuals, or, as they are sometimes termed, partialled scores. These can be expressed most succinctly when the original variables are put in standard score or z score form. In the example cited, if depression is denoted as Variable 1, negativity in reaction to faces as Variable 2, and anxiety as Variable 3, one might denote the partialled depression score as z_{1-3} , which is the residual score computed as the difference between an individual's original depression score and the level of depression predicted on the basis of the individual's anxiety. The prediction is done by linear regression; with variables in standard score form, the predicted score, denoted $\hat{z}$, for a variable is simply the z score on the other variable times the correlation between the two variables. That is,

$$\begin{aligned}\text{depression partialling anxiety} &= z_{1-3} = z_1 - \hat{z}_1 \\ &= z_1 - r_{13}z_3,\end{aligned}$$

where z_1 = standard score on depression; z_3 = standard score on anxiety; r_{13} = correlation between depression and anxiety; z_{1-3} = residual score on depression after variability associated with anxiety is removed.

Similarly, the residual score on negativity in reaction to faces would be

$$\begin{aligned}\text{negativity partialling anxiety} &= z_{2-3} = z_2 - \hat{z}_2 \\ &= z_2 - r_{23}z_3,\end{aligned}$$

These residual scores are uncorrelated with anxiety, and hence their correlation will be unaffected by any linear relationship with anxiety. We can now develop the formula for the partial correlation by substituting these residuals into the conventional formula for the correlation:

$$r_{12.3} = r_{(1-3)(2-3)} = \frac{s_{(1-3)(2-3)}}{s_{(1-3)}s_{(2-3)}}.$$

The denominator terms indicate the variability of the residuals. But note that because the squared correlation between two variables indicates the proportion of variability accounted for, and because the variance of the standardized variables is 1, the standard deviation of each set of residuals is simply the square root of 1 minus the squared correlation between the two variables:

$$s_{(1-3)} = \sqrt{1 - r_{13}^2} \text{ and } s_{(2-3)} = \sqrt{1 - r_{23}^2}.$$

The covariance of the residuals in the numerator is the average of the cross products of the residual scores, which can be written as

$$\begin{aligned}s_{(1-3)(2-3)} &= \frac{\sum z_{(1-3)}z_{(2-3)}}{N} \\ &= \frac{1}{N} \sum (z_1 - r_{13}z_3)(z_2 - r_{23}z_3) \\ &= \frac{1}{N} \sum (z_1z_2 - r_{13}z_2z_3 - r_{23}z_1z_3 + r_{13}r_{23}z_3^2) \\ &= r_{12} - r_{13}r_{23} - r_{23}r_{13} + r_{13}r_{23} \\ &= r_{12} - r_{13}r_{23}.\end{aligned}$$

Substituting these values into the numerator and denominator of the formula for the correlation, we obtain as desired

$$\begin{aligned}r_{12.3} = r_{(1-3)(2-3)} &= \frac{s_{(1-3)(2-3)}}{s_{(1-3)}s_{(2-3)}} \\ &= \frac{r_{12} - r_{13}r_{23}}{\sqrt{1 - r_{13}^2}\sqrt{1 - r_{23}^2}}.\end{aligned}$$

Thus, we have shown that the partial correlation is the ratio of a numerator indicating the covariance of the residual scores from which the third variable has been partialled to a denominator that is the product of the standard deviation of these residual scores.

Issues in Interpreting Partial Correlations

There are several reasons why a partial correlation may not be meaningful or its meaning might be misunderstood. Thus, conceptual and statistical issues that complicate the interpretation of partial correlations must be considered.

First, the residual score computed may not capture the construct of interest. One may, for example, conceive of depression as sharing with anxiety certain psychological processes or symptoms such as negative affect. Removing variability from depression associated with anxiety might then remove core aspects of what

constitutes depression, so that the residual scores are, in fact, considerably less valid than the original scores as a measure of depression. A related issue arises when one of the variables is a discrete variable indicating group membership such as race. One might be interested in knowing whether racial groups would differ in some outcome such as academic achievement if they did not differ in socioeconomic status (SES). Using a partial correlation to shed light on this may be helpful, but it must be kept in mind that the question posed is a counterfactual one (i.e., the facts may be that there are differences across racial groups in SES), and the answer provided implicitly assumes that the relationship between SES and achievement is a strictly causal one, which it may not be. Thus, a partial correlation that estimates the relationship between achievement and racial group membership controlling for SES may not correspond to reality, just as comparing high and low depression groups controlling for anxiety may not be representative of actual groups of depressed and nondepressed people.

Second, a heuristic principle often suggested for understanding the meaning of partial correlations may not apply in a researcher's real-world application. The heuristic often suggested to aid in understanding the meaning of a partial correlation is that it reflects the correlation expected between two variables when a third variable is held constant. The key assumption that assures this heuristic actually holds is multivariate normality. Multivariate normality implies not only that each of the three variables involved has a univariate normal distribution but also that the joint density function of each pair of variables must be bivariate normal. If this is not the case, then the conditional correlation (arrived at by pooling the correlations between the two variables computed within each of the various levels of the third variable) may not correspond to the partial correlation. As a striking example of this, consider the relationship between statistical independence and zero correlation that obtains in the two-variable situation and how this relates to the facts of partial correlations. That is, it is well-known that a zero correlation between two variables does not imply their statistical independence because of the possibility of nonlinear relationships, but it is also well-known that if two variables are statistically independent, they must have a zero correlation. In sharp contrast, it is possible that two variables might be conditionally independent at each level of a third variable, yet their partial correlation controlling for the third variable may be non-zero. This can arise, for example, when there is a nonlinear relationship between the third variable and one of the other variables.

Thus, a third point to keep in mind in working with partial correlations is that conventional partial

correlations control only for linear relationships among variables. If one suspects nonlinearity, higher-order partial correlations may be appropriate. A higher-order partial correlation is computed by statistically controlling for multiple variables simultaneously. In such a situation, you are still computing a correlation between residuals, but the residuals reflect the variability in a variable that is not predictable by any of the variables being controlled for. To extend our original example, one might compute the partial correlation between depression (Variable 1) and negativity (Variable 2), controlling for both anxiety (Variable 3) and gender (Variable 4), with the higher-order partial correlation being denoted $r_{12.34}$. Thus, one way of dealing with suspected nonlinear relationships between a third variable and one or both of the variables of most interest would be to compute a higher-order partial correlation in which one partialled out various powers of the third variable (for example, one might control for not only the anxiety score but also anxiety squared).

Finally, in computing partial correlations, one is removing the effects of a construct only to the extent that one has validly and reliably measured that construct. If one's measure of anxiety is poor, then some effects of anxiety will remain in the variables of primary interest even after the poor measure is controlled for. One common example of such fallibility is when variables are used in research that have been formed by artificially dichotomizing continuous variables. In such a case, the dichotomous variable will have considerably less information about the construct of interest than the original continuous form of the variable. Controlling for such an imperfect measure of a construct of interest can lead to spurious conclusions and result in either positively biased or negatively biased estimates of the strength of the partial correlation between the other variables.

Conclusion

A partial correlation is a potentially very useful measure of the relationship between two variables that remains after the linear relationship of each of the variables with a third variable has been removed. However, because of the potential effects of factors such as nonlinearity, unreliability, and nonnormality, partial correlations must be interpreted with caution.

PARTIAL ETA-SQUARED

Partial eta-squared is an estimate of effect size in conjunction with analysis of variance (ANOVA) and generalized linear model (GLM) analyses. Although there is general consensus about the desirability of reporting estimates of effect size in research reports, there is debate about the relative utility of various options. Relative to other options such as eta-squared or omega squared, partial eta-squared is less well understood and less useful. The recent popularity of partial eta-squared appears to rest on its inclusion in the output of popular statistical software rather than its merits as an informative estimate of effect size.

Many social scientific journals require reporting estimates of effect size to supplement tests of statistical significance, and such reporting is considered good practice by most commentators. An effect size is a standardized estimate of the magnitude of a difference or the degree of association that is relatively independent of sample size. Simply put, estimates of effect size are designed to reflect how strongly two or more variables are related, or how large the difference is between groups. Cohen's *d*, the correlation coefficient *r*, and the squared multiple correlation *R*² are examples of estimates of effect size. For ANOVA, omega squared, epsilon squared, and eta-squared are common estimates of effect size. Partial eta-squared is an estimate of effect size. This entry describes the calculation of partial eta-squared and discusses several issues associated with reporting partial estimates of effect size.

Calculation

Partial eta-squared is calculated by dividing the sum of squares for a particular factor, which could be either a

main effect or an interaction, by the sum of squares for the factor plus the sums of squares error for that factor as shown in Equation 1:

$$\text{partial } \eta^2 = \frac{SS_{\text{between}}}{SS_{\text{between}} + SS_{\text{error}}}. \quad (1)$$

Partial eta-squared can also be calculated from an *F* test, as shown in Equation 2:

$$\text{partial } \eta^2 = \frac{n_1 F}{n_1 F + n_2}. \quad (2)$$

Equations 1 and 2 are equivalent, and both equal the squared partial correlation when there are two levels of the independent variable.

$$\eta^2 = \frac{SS_{\text{between}}}{SS_{\text{total}}}. \quad (3)$$

In one-way ANOVA, partial eta-squared and eta-squared will always be exactly equal. This is because there are no other factors to partial. In multi-way ANOVA, however, the two values depart, sometimes radically. Partial eta-squared is always greater than or equal to eta-squared, and the discrepancy is a function of the number of factors in the design; the effects of the other factors on the dependent variable; and if the design involves only independent groups factors, or whether some factors are repeated. Partial eta-squared will be increasingly larger than eta-squared as the number of factors in the design increases, as the effect sizes for the other factors increase, and as the proportion of factors that were repeated measures increases.

Whereas cumulated eta-squared values for a particular dependent variable can never sum to more than 1.00, partial eta-squared has no such limitation. That is because eta-squared consistently uses the total sum of squares for the dependent variable in the numerator. Every explanatory factor can account only for unique variance partitioned from the total variance in the dependent variable. This makes sense in experimental designs where components of variation are orthogonal. Partial eta-squared has only the sum of squares for the effect and the error sum of squares in the denominator. Thus, each factor has a unique denominator for the effect size calculation. Each calculation of partial eta-squared has its own upper limit that approaches 1.00 (when there is essentially no variance left as unexplained or error). Thus, the theoretical upper limit for cumulated partial eta-squared values is the number of factors, *k*. That is, if there are four factors in the design, their eta-squared values can sum to 1.00, whereas their partial eta-squared values can sum to 4.00.

Partial eta-squared is sometimes misreported as eta-squared. Examples of misreporting are obvious when the effect sizes labeled as eta-squared account for a percentage of variance in a dependent variable exceeding 100%. This is not possible when calculating eta-squared but can occur when using partial eta-squared. This reporting error can result from a problem with some versions of SPSS incorrectly labeling partial eta-squared as eta-squared. The problem, however, can also occur with other statistical software. Thus, the problem does not appear to be specific to a particular field of research nor a particular software package.

Issues Concerning Reporting Partial Estimates of Effect Size

One key to understanding the comparative desirability of reporting partial versus non-partialled estimates of effect size lies with the difference between conceptualizing design factors as inducing variance versus explaining variance in the dependent variable. If research designs differ by adding additional experimental manipulations, a case can be made that the additional factors caused increased variance in the dependent variable between those two studies. Thus, one would not expect a factor in a two-way ANOVA to account for as much variance in the dependent variable as the same factor in a one-way ANOVA because of the increased sum of squares value in the former case. Under the condition that one was convinced that the effects of additional factors caused additional dependent variable variance, it could be reasonable to use partial eta-squared as a comparable index across studies with different numbers of factors. That is, partial eta-squared is useful for comparing effects for the same factor tested across different designs when the designs differ by additional experimental inductions that cause increased total variance. However, if an attribute variable such as sex is used as a factor, it cannot be claimed to have caused differential dependent variable variance across designs. Thus, it would not be appropriate to partial that component of variance out of the effect size calculation across designs. A non-partialled eta-squared would be advised. Overall, then, only additional induced sources of variance should be removed from the denominator when making comparisons across studies. To that end, generalized eta-squared has been proposed, which partials out only sources of induced variance. Although partialling effects for the purpose of direct, across-design comparisons is conceptually sound, in practice, it is difficult to know for sure if additional factors instill variance, explain existing variance, or both. For this

reason, when partial eta-squared or generalized eta-squared is reported, it is advisable to report eta-squared as well.

A second issue relates to the conceptual meaning of partialling out orthogonal factors. A common use of a partial correlation is eliminating spurious effects attributable to other independent variables. In survey research, for example, the different predictor variables are typically correlated, and it makes sense to statistically control some independent variables. In factorial experimental designs, however, where partial eta-squared is most often reported, the other independent variables are nearly orthogonal. Partialling the effects of an orthogonal, non-control variable has a different substantive interpretation.

A third issue related to which estimate of effect size to report relates to the usefulness of each for later meta-analyses. Meta-analysis typically requires zero-order indexes of effects such as r or d . Thus, indexes that control for (i.e., partial) other factors such as partial regression coefficients and partial eta-squared are of less use in these cumulative studies. Given the tendency of partial eta-squared to substantially overestimate an effect as design complexity increases, including these effect size statistics in a meta-analysis could lead to erroneous determinations of heterogeneous effects or identification of moderators that do not exist. These problems are especially relevant when attempting to convert reported F values to r . The typical formulas used for this conversion lead to partial correlations rather than zero-order correlations when there was more than one ANOVA factor. Thus, the effect sizes derived from F are of little use in meta-analysis. Craig R. Hullett and Timothy R. Levine provided a method for accurately estimating zero-order effects from data typically presented in research reports as a means for overcoming this limitation. Of course, it would still be reasonable to include partialled effect sizes if they met the previously stated condition of controlling only for additional induced variation in the dependent variable. Otherwise, partialled effect sizes have less value for current methods of meta-analysis.

A final issue relates to confidence intervals. Confidence intervals are a function of the standard error of whatever statistic is being reported. They require knowledge of the sampling distribution for the statistic. The sampling distributions of eta-squared and partial eta-squared are not equivalent. Although they do not go into detail about the differences between the distributions, one can logically infer from parallel statistics the elements that will affect the difference in standard errors. For example, a regression coefficient from a design in which there are multiple independent variables has a

standard error that increases as the number of additional variables increases, as the correlation among the predictors increases, and as the total explained variance by all included variables decreases. One would expect similar consideration when determining the standard error and, thus, the confidence intervals around partial eta-squared. To date, though, no published information appears to exist detailing how such elements should be considered in calculating confidence intervals around partial eta-squared. Without such knowledge, one cannot come to a clear conclusion about whether a partial eta-squared should be considered a good or poor estimate of effect in the population.

Final Thoughts

Partial eta-squared is an increasingly popular estimate of effect size reported by popular statistical software programs in conjunction with ANOVA and GLM analyses. The purpose of partial eta-squared is to provide an estimate of effect size for comparing the effects of a factor across studies with different research designs. Its usefulness, however, is limited by several considerations. Therefore, it should be reported as a supplement to, but not a substitute for, eta-squared or omega squared.

PARTIAL FACTORIAL INVARIANCE

In social and behavioral sciences, when multiple items are used to measure one construct, the condition of measurement invariance implies that the relations between the items and the constructs are the same across different groups and settings. In other words, there is no measurement bias due to group membership. Under the common factor model, which hypothesizes that the shared variances of the items can be attributed to one or more latent factors that coincide with the constructs of interest, factorial invariance refers to the condition that all items relate to the latent factors in the same way across subpopulations, such as demographic subgroups, time points, and measurement conditions. Partial factorial invariance (PFI) happens when only a subset of items function similarly across subpopulations. Because quantitative research can only be as good as the measurement of its variables, the presence of PFI can result in severe bias in statistical inferences and conclusions. This entry provides the formal mathematical definition of PFI, describes the three types of PFI and how each of them biases statistical inferences, and discusses methods for detecting PFI and adjusting for it.

Formal Definition

For simplicity, it is assumed that there is only one target construct of interest, but the discussion here would generalize to multifactor situations. The common factor model hypothesizes that the score of an item, Y_j , is a linear function of the latent factor being measured, η , and a measurement error component, E_j , such that

$$Y_j = v_j + \lambda_j \eta + E_j,$$

where η represents the component that is shared across all items purported to measure the same latent construct and E_j is the *unique factor* that is not shared with other items. In practice, researchers commonly assume that E_j is normally distributed with mean 0 and variance θ_j . Thus, the model parameters that determine the relations between the items and the latent factors in the above equation are

1. λ_j : factor loading (i.e., slope)
2. v_j : intercept
3. θ_j : uniqueness

PFI happens when the measurement parameters of some items are different across groups.

Types of PFI

Three types of PFI can be distinguished; each corresponds to nonequivalence of one set of measurement parameters: partial metric invariance, partial scalar invariance, and partial strict invariance. In partial metric invariance, the factor loadings of one or more items are different across subpopulations. As shown in Figure 1, partial metric invariance implies incomparable Y scores across subpopulations, with different magnitudes of bias across levels of η .

In partial scalar invariance, the intercepts of one or more items are different across subpopulations while their factor loadings are the same across groups. As shown in Figure 2, partial scalar invariance implies that one subpopulation consistently has higher/lower scores on the noninvariant items.

Figure 1 Partial Metric Invariance

Figure 2 Partial Scalar Invariance

In partial strict invariance, the uniqueness of one or more items is different across subpopulations while their factor loadings and intercepts are the same across groups. This implies that the measurement error is constantly larger in some subpopulations than in others.

Partial metric and partial scalar invariance have received more attention in the literature because they correspond to systematic biases in the observed score Y , leading to incomparable observed scores across subpopulations. If partial metric or partial scalar invariance is found with respect to a grouping variable (e.g., gender, ethnicity, culture), any comparisons of the construct across levels of the grouping variable are compromised if appropriate adjustments are not made. The consequences range from biased estimates of group differences, false detection of group differences when none exists (or vice versa), to complete reversal in the directions of group differences.

As an illustrative example, consider a psychological test with five items (with scores of 0–4) measuring life satisfaction. When evaluating factorial invariance across a U.S. sample and a Chinese sample, researchers find that the test has partial metric invariance; specifically, the factor loadings for Item 5 are, respectively, 1.0 for Americans and 0.5 for Chinese. If an American and a Chinese participant, both having a score of $\eta = 1$ on the latent life satisfaction metric, are compared, the Chinese would have a Y score that is 0.5 points lower. Thus, researchers may find that U.S. participants have higher life satisfaction on average based on the test scores, but the difference may be only due to partial metric invariance.

Methods to Detect PFI

Methods to detect PFI generally rely on the confirmatory factor analysis framework. Specifically, for each type of PFI, a hypothesis that a set of parameters are the same across subpopulations is tested. The null hypothesis for testing partial metric invariance is

$$H_0: \lambda_{j1} = \lambda_{j2} = \dots, \text{ for all items.}$$

The likelihood ratio test, for example, can be used to compare the models without and with the equality constraints on the loadings, and a significantly better fit of the model without equality constraints provides evidence for the presence of partial metric invariance. If there is no evidence for noninvariant loadings, researchers then proceed to test the null hypothesis for partial scalar invariance:

$$H_0: v_{j1} = v_{j2} = \dots, \text{ for all items,}$$

and similarly, for partial strict invariance if there is no evidence for noninvariant intercepts.

If there is any evidence for PFI, a follow-up analysis is needed to adjust for the subsequent group comparisons, either by removing the noninvariant items or by comparing the latent means in confirmatory factor analysis with equality constraints only on the invariant items. To do so, one needs to identify the noninvariant items, which usually involves a sequential specification search that iteratively tests individual parameters. The specification search can start from the fully unconstrained model (also called the *configural model*) and gradually add constraints, or start from the fully constrained model (i.e., strict invariance model) and gradually relax the constraints.

Implications for Designing Research

Given that failures to take into account PFI can lead to erroneous research conclusions, when choosing psychological tests for a research study that involves comparisons of subpopulations, researchers should opt for tests that are less affected by PFI with respect to the grouping variables of interest. Also, because full factorial invariance is rarely found in practice, researchers should evaluate the impact of PFI in their samples before proceeding to group comparisons and adjust for PFI when necessary.

(e.g., test, survey, or questionnaire) that measures a latent construct with observed indicators. Full measurement invariance signifies that *all* of the parameters that determine the empirical relations between the indicators and the construct are equal for any given measurement condition (e.g., different time points or groups) and that the relations are not condition-specific. If full measurement invariance is achieved, then the differences in subjects' observed scores are due to differences in the latent construct rather than a condition-specific variable that systematically influences the responses. It is required whenever researchers use a measure's observed composite scores to compare conditions (e.g., pre- vs. posttest, men vs. women) or use scores to rank or compare subjects from different populations (e.g., for educational purposes). However, measurement parameters can vary across conditions. Partial measurement invariance (PMI) refers to a situation in which only some, but not all, of the parameters are equal across conditions of use of an instrument. Measurement invariance can be considered a matter of degree in that a subset of parameters can be invariant while others are not, and an instrument can be partially invariant.

A lack of measurement invariance is a concern in social science research because some statements on questionnaires (i.e., items) may have different meanings across time and groups, complicating the interpretation of responses to those statements. For example, the question "Who is the president of the United States?" on a general measure of intelligence will have a different level of difficulty and a different meaning to a U.S. sample versus that of any other country. If researchers use a latent factor model (e.g., structural equation modeling [SEM] or item response theory), they can relax the assumption of full invariance by determining which items are noninvariant and then allowing those items to vary across conditions. These partially invariant models enable researchers to account for measurement differences across conditions and allow them to estimate latent scores on the construct rather than analyzing observed scores, which do not account for the measurement differences. If researchers correctly identified all noninvariant items and at least two items are invariant, they may retain all items and use estimates from these models in subsequent analyses. The remainder of this entry presents methods to evaluate PMI and provides options of statistical analyses that may be carried out in case of PMI.

PARTIAL MEASUREMENT INVARIANCE

Measurement invariance, also referred to as *measurement equivalence* or *lack of differential item functioning*, is a term used to describe a property of an instrument

Evaluating PMI

The two methods of evaluating measurement invariance that have received the most application and attention so far are multiple group confirmatory factor

analyses and item response theory. The term *PMI* is typically used with multiple group confirmatory factor analyses methods.

In factor models, the observed item response (x_i) is modeled as a linear function of the latent factor (i.e., the construct) η .

$$x_i = \tau_i + \lambda_i \eta + \varepsilon_i.$$

The parameters in this equation are the intercepts τ_i , denoting the expected mean of item i , controlling for the latent factor η , the loadings λ_i , determining the relationship between the item and the latent factor, and the items' error term ε_i . The measurement parameters τ_i , λ_i , and ε_i are the focus of PMI investigations. In data in which subjects' observations differ on a certain condition, invariance of these parameters is investigated by fitting a series of hierarchical, nested models in which these parameters are constrained to be equal across conditions. A bottom-up approach is commonly adopted during which the fit of the models to the data is evaluated in the following steps.

First, the basic configuration of the items on the factors is tested for equality across conditions (configural invariance). If this model has an acceptable fit, then the nested model constraining the loadings to be equal is tested (metric invariance). Two subsequent models add restrictions on item intercepts (strong invariance) and error terms (weak invariance) across conditions to each previous model, respectively. The models are compared against each other using an X^2 difference test, where a significant p value indicates that a more restrictive level of invariance may not be tenable. Noninvariant parameter estimates will result in a poorer-fitting model when constrained to be equal, and a more restricted model will fail to demonstrate acceptable fit if there are noninvariant items. Researchers can then work to identify a PMI model and consider which items are noninvariant with respect to their loadings, intercepts, or error terms by examining the modification indices or residual covariance matrices of the more restricted model. To improve the model, they can release the restriction on the parameter with the highest modification index or residual estimate. Often the source of misfit concerns several items. Statistical software can simultaneously estimate a partially constrained model for each item, freeing the restriction on the parameter of the level where invariance was rejected (i.e., loading, intercept, or error term), and compare the partially invariant model of each item to the fully restricted model using an X^2 - difference test. A significant p value indicates that releasing the restriction on the item results in a significant difference in the model. This test statistic is corrected for multiple testing in which the number of tests equals the number of items. If several comparisons

are significant, the model that yields the greatest improvement of the chi-square test statistic is selected. In a subsequent step, the model with this noninvariant item is again compared to several partially constrained models in which the remaining items are freed, respectively. This procedure is repeated until there are no more significant differences between models.

Determining the Anchor Items

Since PMI allows for parameters to vary across conditions, the multigroup model requires more parameters than a regular factor model. This requires additional steps for model identification, beyond what is typically applied in CFA. To test for PMI, researchers need to constrain a set of parameters across conditions, such that at least one item is invariant. This so-called anchor item remains restricted across the measurement invariance models that are tested. The estimation of other parameters is dependent on the anchor item, so it is necessary to carefully select an item that is noninvariant. This can be done with different statistical procedures such as a factor ratio test and the stepwise partitioning procedure. This causes a need for multiple testing, so it is recommended to evaluate anchor items based on theoretical considerations as well.

How to Respond to PMI

Once the noninvariant items are identified, the researcher can determine the final PMI model that applies across conditions. For example, if full intercept invariance was rejected and the source of noninvariance was identified, a PMI model would specify equal factor configuration and loadings across conditions but allow the intercepts of the items that are noninvariant to vary across conditions, as well as all items' error terms. The next section describes the consequences of PMI on observed scores and how to proceed with observed and latent models to investigate substantive research questions.

Observed Scores

When there is PMI, observed scores can be biased. The amount and direction of the bias depend on the pattern and magnitude of the noninvariance. Though this is an active area of methodological research, findings suggest that partially invariant loadings will bias the observed factor variances and partially invariant intercepts will bias the observed factor means. When the residual terms are noninvariant, observed scores will also bias reliability estimates. If researchers are interested in comparing variances or investigating the

relationship of the scores to other constructs (e.g., estimate correlation and regression coefficients), they should ensure full loading invariance. If one wants to compare observed score means or determine prevalence rates between conditions, full invariance of both loadings and intercepts has to be established. When these requirements are not fulfilled, researchers are advised to proceed with statistical analyses in a latent factor model framework, which can be done using SEM.

SEMs and Factor Scores

SEMs can be used to obtain unbiased estimates of the group means and variances when observed scores are biased due to PMI. How to use these models for subsequent analyses depends on the research questions and the statistical analyses researchers are interested in. If loadings are noninvariant, fitting partially invariant SEMs, where noninvariant items are freely estimated across groups, are recommended to get unbiased estimates of factor variances and covariances. To determine the relationship to other constructs, the model can be extended by adding paths to exogenous variables to estimate unbiased regression coefficients. In the case of intercept differences, groups should be compared on their latent means in a partially invariant multigroup factor model that allows for different intercepts across groups. In PMI models, the latent factor is typically scaled by choosing one condition as the reference group, and fixing the mean of this group to 0 and the variances to 1. The mean of the other group is an unbiased estimate of difference between conditions rather than measurement differences. This approach is a *simultaneous* one where the parameters are directly interpreted from the model. Another option is the *multistage* approach where one first obtains factor scores from the PMI model and uses them for downstream statistical analyses such as *t*-tests, analyses of variance, and regression models. Those scores are corrected for measurement error as well as measurement differences across conditions and can be interpreted as *z* scores if the latent factor has been scaled by setting the mean to 0 and variance to 1 in the reference group. Comparing the results from analyses conducted with factor scores to those obtained with the original observed scores gives an estimate of how sensitive the results are to measurement noninvariance.

PARTIALLY RANDOMIZED PREFERENCE TRIAL DESIGN

Partially randomized preference trials (PRPTs), using Brewin and Bradley's design, are a product of combining the best elements of randomized controlled trials (RCTs), which involve random allocation of different treatments to willing patients, and feasibility studies, in which patients choose their preferred treatment. PRPTs give patients, who are recruited into a clinical trial, the option to choose their preferred method of treatment, and if the patients have no strong motivation toward a specific treatment, they are asked if they will agree to random allocation to one or another treatment method. All patients recruited into the PRPT need to be given clear, accurate, and detailed information about what the treatments to be offered in the trial involve. They can then make an informed decision when given the opportunity in the PRPT to choose a preferred method of treatment. PRPTs can be used to evaluate many different types of treatment, including medical treatment, psychological treatment, and dental treatment, or a

combination of treatment types, for example, drug versus psychological treatment for depression.

This entry first details the structure of a PRPT and variations of the structure. Next, this entry discusses validity (external and internal), the acceptability of PRPT to patients, and PRPTs' advantages and limitations. Last, this entry describes the appropriate implementation of PRPTs.

Structure

In a PRPT comparing two treatments, there are potentially four separate groups of patients, each receiving one of the two treatments, usually an established treatment and a new treatment. Patients are informed about the two treatments being compared and asked if they have a strong preference. Patients who have strong preferences for one treatment over another are allocated to a group in which they can have their preferred method of treatment. In Figure 1, patients who are particularly motivated toward the new treatment are allocated to Group 1, and patients who would prefer to use an established method of treatment are allocated to Group 2. Patients who have no strong preference and are equally prepared to use either treatment are said to be in equipoise and, with their consent, have one or the other treatment type assigned randomly and are thereby allocated to either Group 3 or Group 4.

Variations on the Structure

Three-group trials may result if no one has a strong preference for one of the treatments. A very small number of patients in one of the preference groups (Groups 1 or 2 in Figure 1) may not be analyzable statistically

but will still serve an important purpose in removing those with preferences from Groups 3 and 4, where randomization to a nonpreferred treatment would lead to disappointment.

If all the patients who are recruited into the PRPT have a strong preference, a feasibility study will result where all patients chose their treatment, and if no recruit has a strong preference, an RCT will result. However, if an RCT results from patients not having a preference for a particular treatment offered, it will differ from that of many conventional RCTs as motivational factors will not distort outcomes. In a conventional RCT, some patients may agree to randomization with the hope of obtaining a new and/or otherwise inaccessible therapy. Patients who think they would prefer a new treatment (those who are allocated to Group 1 in a PRPT) may have been included in an RCT if the new treatment was unavailable outside the trial and participation in the trial was their only way of obtaining their preferred method of treatment. However, RCT participants are asked to accept any of the health care options being compared. Inclusion of patients preferring the new treatment over a standard treatment will bias the RCT sample in favor of the new treatment; those with preferences for the standard treatment are more likely to decline to participate in an RCT as they can usually obtain their preferred treatment outside the trial. The RCT sample recruited will be randomized to two groups. When preferences for the new treatment are marked, one group will contain participants who are pleased to receive the new treatment whereas the other group will contain individuals who are disappointed that they have not been allocated to the new treatment (as demonstrated empirically by Feine and colleagues in 1998 and discussed by Bradley

Figure 1 The Structure of a Partially Randomized Preference Trial (PRPT)

in a commentary the following year). When the majority of recruits have a preference for the new treatment, an RCT creates groups that have been allocated at random but differ in respect to motivation to use the treatment assigned. The control group of participants who have been randomized to the standard treatment will contain patients who are disappointed with the treatment allocation and therefore will be more likely to drop out of the trial. They may also be less likely to follow the treatment recommendations and do less well with the treatment than they would have done if motivated to use that treatment. If disappointed patients drop out of the control group, outcomes of the control treatment will be artificially improved, minimizing any advantages of the new treatment. However, if such poorly motivated patients remain in the control group, outcomes will be worsened, thereby exaggerating the advantages of the new treatment.

External Validity

People who refuse to take part in an RCT are more likely to have strong preferences, and some participants may have strong opinions regarding the relative acceptability of the treatments being compared. People refusing to take part in an RCT because they do not want to risk being randomly allocated to a nonpreferred treatment are more likely to take part in a PRPT. Few patients invited to participate in PRPTs decline to do so (e.g., only 3 of 373 women invited declined to participate in Henshaw and colleagues' 1993 study using the PRPT design). Participants who accept an invitation for an RCT may be a minority of those invited—sometimes fewer than 20%. Within RCTs, recruitment success can vary markedly from center to center, as in the World Health Organization trial of continuous subcutaneous insulin infusion pumps versus intensified injection regimens for Type 1 diabetes in the early 1980s, where recruitment ranged from 70% in Albania to 20% in Paris. An RCT may fail to recruit patients who prefer a treatment available outside the trial, and for those who are recruited, randomization may create differences between groups—one being disappointed whereas the other is pleased with the treatment allocated at random. Patients recruited to a PRPT, on the other hand, are likely to be the vast majority of those invited, and the results obtained will therefore be more generalizable to the population of eligible patients. Patient preferences act to reduce the recruitment of patients into RCTs (as patients fear randomization will allocate a nonpreferred treatment) and thus reduce external validity of RCTs. External validity is improved by using a PRPT design, where patients know any strong preference will be met, and hence recruitment is usually close to 100%.

Internal Validity

Not only is recruitment success greater in PRPTs compared with RCTs, but dropout rates of PRPTs are also lower in both the randomized and preference arms than are commonly found in RCTs. As more participants drop out of RCTs, the randomization process is increasingly undermined and the groups are less comparable. With PRPTs, the randomized groups have been cleared of preferences prior to randomization, and the preference groups, being self-selected anyway, are not threatened by any few dropouts that may occur.

The importance of PRPTs and patient choice of treatment are especially apparent when considering the best treatment for chronic illnesses, such as diabetes, where patient motivation is essential and factors such as the convenience and flexibility of treatment regimens can dramatically improve quality of life as seen in the DAFNE (Dose Adjustment for Normal Eating) trial. Motivation is more likely to influence outcome when there is a greater need for patient participation in their treatment, which may involve diet adjustment, self-monitoring, and self-medication regimens. When patients play such an active role in treatments and treatment impacts on lifestyle, results may be misleading if conclusions are drawn from patients who were allocated to a method of treatment they did not want (i.e., in many RCTs). Psychological and biomedical outcomes of treatment are likely to be improved when patients' preferences are matched to treatment, especially when the biomedical outcomes of the treatment are dependent upon participative interventions.

Acceptability to Patients

The PRPT method improves treatment outcomes by increasing the chances of meeting the needs of individual patients by establishing which treatment is most suitable for a particular patient in his or her individual circumstances. Differing needs, priorities, and motivation are variables that can influence individual patient choices for medical and other treatments. There are also demographic, clinical, and biochemical variables that may influence which type of treatment is best suited to different patient subgroups.

People who design clinical trials are increasingly showing greater interest in patients' views and the impact of treatments on quality of life and other patient-reported outcomes. Such outcomes are usually facilitated by matching preferences with treatment. Although initially the PRPT was seen as a compromise to be used when many patients could not be persuaded to accept randomization to treatments about which they had strong views, now the PRPT is more often

recognized as the design of choice, superior to an RCT when patients have strong preferences, and superior to an entirely unrandomized feasibility study when at least some patients can be randomized without risk of disappointment.

Advantages of PRPTs Compared With Feasibility Studies

In feasibility studies, patients chose their own method of treatment from two or more options offered. Various physiological, psychosocial, demographic, and other characteristics of patients can affect the type of treatment that individual patients opt for and can therefore affect treatment outcomes and conclusions drawn from the trial. For example, in an obesity trial comparing a drug treatment and a diet treatment, patients who choose the drug treatment may do so because they have tried many diets and have failed to lose weight by dieting, whereas individuals who opt for the diet treatment may not have tried to diet before and may therefore anticipate more success. Such psychosocial factors are likely to influence individuals' motivation to use a particular treatment method from the outset of treatment. Individual differences in psychosocial factors may have a marked effect on the success of each treatment for an individual patient. The motivation to follow the treatment recommendations by patients who opt for the diet treatment would be greater than that of those individuals who had little faith in dieting. This motivational effect would enhance the advantages of both treatments in a self-selected sample. However, it is difficult to draw conclusions from feasibility studies about the value of treatments to patients who have no preferences. By interviewing patients and/or eliciting questionnaire data, the reasons patients have for choosing a particular treatment can be determined in both feasibility studies and PRPTs. However, the randomized subgroups in PRPTs allow for the treatments to be compared in groups where motivational factors and other baseline characteristics can be expected to be similar before and after randomization.

In feasibility trials, treatment groups may include individuals who have a strong preference for that treatment over the alternative treatment and individuals who had no preference but had to decide on a method of treatment. Patients involved in a PRPT are not pressured to choose a particular type of treatment. Only those individuals with strong preferences are allocated to the treatment group preferred; patients who do not have strong preferences are asked if they would agree to be randomized. The randomized and preference groups of the PRPT allow comparisons to be made at baseline to look for and measure differences between

randomized and nonrandomized groups using each treatment in the trial with a view to understanding any between-group differences in outcome.

Advantages of PRPTs Compared With Randomized Controlled Trials

RCTs are currently viewed by the majority of medical researchers as the gold standard for clinical trial design, and a lack of randomization is usually seen as a weakness or flaw in a study. The assumption that RCT designs are the only acceptable way to conduct clinical trials may have led to some new treatments being used without evaluation and studies to remain unpublished because randomization was deemed to be unsuitable or unethical or was refused by patients. These studies might take place using a PRPT where ethical approval and patient acceptance could be gained from the incorporation of an element of choice of treatment type in the design.

Randomization aims to avoid the limitations of a feasibility study such as the introduction of selection bias, which can affect comparability of treatment groups and different patient characteristics affecting treatment choice. However, most proponents of RCTs have wrongly assumed that randomization always produces comparable groups and have overlooked the fact that randomization itself can create between-group differences as a result of disappointment effects. The PRPT design aims to deal with the limitations of an RCT, optimizing motivational factors in those with strong preferences and equalizing motivational factors in the randomized groups within the PRPT. The effects of motivational factors on treatment outcome can be considered by comparing those who chose a treatment with those who were content to accept randomization.

Larger numbers of participants are likely to be recruited into a PRPT over an RCT, especially in certain areas of medicine such as gynecology and obstetrics, where preferences are strong. In a clinical trial comparing treatments for menorrhagia conducted by Cooper and colleagues, the majority of women recruited (97%) agreed to participate in the PRPT design compared with 70% who agreed to take part in the conventional RCT. The 40% relative increase in participants agreeing to participate in the PRPT suggests an increase in perceived acceptability of a PRPT over an RCT where patients are likely to have strong views concerning treatment.

It is more difficult to recruit patients with a preference for a conventional treatment readily available outside the trial. Therefore, the majority of participants in an RCT will be biased in favor of the new treatment and less likely to make a nonpreferred treatment work as well as a preferred treatment. In RCTs, people are

likely to be more disappointed if allocated to the conventional treatment group, and this problem is likely to arise whenever a new treatment is only available to patients within a clinical trial. Therefore, the overall sample studied in a PRPT or in a feasibility study is likely to be more representative of clinical reality and less biased by the effects of experimental manipulation. The disappointed patients in an RCT who are randomized to the nonpreferred, conventional treatment, if they remain in the trial, are more likely to stop following the standard treatment recommendations and do less well, leading to artificially advantageous conclusions favoring the new treatment. The extent of the advantage overestimation will be dependent upon the proportion of disappointed patients who remain in the trial. If these disappointed patients drop out, outcomes will be artificially improved in the randomized conventional treatment group (Group 4 in Figure 1). Outcomes of PRPTs are likely to be more successful than those found in a conventional RCT as the patients in a PRPT with strong views are generally more likely to make their treatment work. Torgerson and colleagues recommend as an alternative to PRPTs that preferences be measured in RCTs and subgroup analyses conducted to examine the impact of preferences. However, the RCT may lose patients with the strongest preferences at least for the standard treatment and maybe for both treatments, who then won't be available for such analyses, biasing the conclusions of the RCT. Thus, although Torgerson and colleagues' approach may enhance the value of RCTs, it does not provide a substitute for PRPTs.

Limitations

The cost difference between a clinical trial that uses an RCT design and one that uses a PRPT design is sometimes cited as a reason for opting for a conventional RCT design. More resources are required by a PRPT as twice as many groups are potentially involved in the trial compared with those included in an RCT. Patients who had a preference for the control treatment are followed up in a PRPT. These patients would probably not be recruited or followed up in an RCT. Patients with a preference for the new treatment unavailable to them outside the trial would probably be recruited into an RCT, but disappointment effects can result and distort the findings of an RCT.

The cost savings of an RCT must be weighed against the loss of internal and external validity due to having a nonrepresentative sample and outcomes that are potentially distorted by disappointment effects. Even when disappointment effects in an RCT are minimized to those of a PRPT (i.e., when both treatments being

compared are available outside the trial), the PRPT still retains the advantage of recruiting a representative sample, not just those willing to be randomized, but also those with strong preferences who would decline to participate if it meant they might be randomized to a nonpreferred treatment.

Implementation

There are several steps that need to be followed by clinical trialists to ensure a PRPT design is implemented appropriately. Patients must be given detailed and accurate information about all the treatments that are available in the trial, including the possible side effects and likely effects of treatment on lifestyle and quality of life. Only when such information is provided can patients make judgments about which treatment, if any, they prefer. Patients should then be asked if they have a strong preference for one or another treatment *before* they are asked if they are willing to have their treatment determined at random. Patients with strong preferences are then allocated to their preferred treatment group and the remaining patients are said to be in equipoise; they have been informed of the treatments but have no clear preference and can have treatment allocated at random to create two comparable groups.

If the procedure used to recruit patients in a PRPT fails to achieve equipoise in the patients who have treatment allocated at random, the randomization process cannot create two similar groups for comparison. Consider, for example, Henshaw et al.'s article that reported a PRPT design comparing medical versus surgical abortion. The trial was presented the trial to patients in a patient information sheet as if it were a conventional RCT. If patients refused to participate, then the clinician informed them they could, in fact, have their preferred treatment. However, it is likely that not all patients with strong preferences will decline to be randomized, particularly if they believe that their preferred treatment is only available within the trial. The randomized groups may therefore have contained patients with strong preferences, and if so, those groups will not have been comparable. Disappointment effects may have distorted the findings from the randomized groups compared with the results from randomized groups including only patients in equipoise. The impact of disappointment effects in this trial of different methods of pregnancy termination is likely to have been less than would be the case for participative treatments for long-term conditions where disappointment may impact on adherence and impair biomedical outcomes as well as quality of life and other patient-reported outcomes. Despite these concerns, the procedures used by Henshaw et al. have been followed by many

subsequent trialists adopting the PRPT design to study more participative treatments.

A systematic review of 32 trials that took account of preferences was reported in the *Journal of the American Medical Association* by King and colleagues in 2005. Twenty-seven of these trials used PRPT designs referred to as “comprehensive cohort trials,” and five were referred to as “two-stage randomized trials” involving an initial randomization to PRPT or RCT and then subsequent randomization within the RCT or for those patients in equipoise within the PRPT. The 32 trials covering a range of clinical areas (gynecology, depression, and cancer among them) included some PRPTs that were inappropriately implemented and others where implementation was insufficiently well specified to determine appropriateness. Trialists did not usually report whether or not the treatments under investigation in the trial were available outside the trial, and it was unclear whether patients believed the treatments to be available outside the trial. If patients assumed that a new treatment under investigation was only available to them within the trial, those with a strong preference for the new treatment would have been likely to agree to take part in the trial and undergo randomization (if they were not initially asked if they had a preference) in order to have a 50% chance of obtaining the new, preferred treatment. Those with a preference for the standard control treatment may assume they could have that existing treatment outside the trial and decline to participate. This is where optimally conducted PRPTs are necessary to avoid disappointment effects and treatment-related attrition that undermine RCTs. Critiques of King et al.’s review point out that the authors overlooked the critical difference between the randomized arms of an RCT, which, when the treatments are not both available outside the trial, may be biased by disappointment effects and dropouts, and the randomized arm of a PRPT where, when properly implemented, patient equipoise is achieved and biases eliminated.

In those trials that included a description of allocation of intervention among those reviewed by King and colleagues, the majority followed Henshaw and colleagues’ example of only offering participants a choice of treatment if they refused randomization. The likely result is the inclusion of patients with preferences (who did not refuse randomization) in the randomized groups and therefore randomized groups that were not in equipoise.

The randomized groups within PRPTs should not be assumed to be the same as those in a conventional RCT. Properly conducted, the randomized groups in a PRPT will be cleared of patients with preferences, leaving only those in equipoise and removing the risk of

disappointment effects that are seen in RCTs when patients have preferences. Even improperly conducted PRPTs that only offer choice when patients decline randomization will have a reduced risk of disappointment effects compared with those seen in RCTs. If one wishes to examine the impact of patient preferences on the outcome of trials, one needs to compare the randomized groups of a properly conducted PRPT (where patients have no strong preferences) with randomized groups in an RCT of the same new treatment only available within the trial and that patients are keen to use. The RCT groups will include patients with preferences, and disappointment effects will be likely in the group allocated to the nonpreferred standard control treatment. Two-stage randomized trials where patients are unaware of the initial stage of randomization to a PRPT or RCT design are ideal for comparing the randomized groups of a PRPT with those of an RCT, but differences should only be expected when at least some patients have strong preferences for one of the treatments that is only available in the trial. If treatments are believed by patients to be available outside the trial, even the randomized groups of an RCT may be free of disappointment effects as those with preferences decline randomization and seek their preferred treatment outside the trial. Proponents of PRPTs consider King et al.’s conclusions that RCTs remain the gold standard and that intervention preferences appear to have limited impact on the external or internal validity of randomized trials’ to be unjustified and misleading. The preferred method of determining the impact of preferences on outcomes of randomized trials is to compare the randomized groups of a well-conducted PRPT (cleared of preferences) and the randomized groups of an RCT where preferences remain and can be disappointed at randomization rather than the method employed by King et al., which compared preference groups assigned to their preferred treatment with randomized groups who had few, if any, preferences to be thwarted, from within the same PRPT.

Optimal Use

In a PRPT, participants are given a choice of treatment and only those without a strong preference (i.e., in equipoise) are asked if they will be randomized—all others being given their preferred treatment. This ensures that no one of those in the randomized arms is likely to experience the disappointment effects often experienced in conventional RCTs and dropouts will be kept to a minimum. The PRPT design is particularly important in the treatment of long-term conditions, participative treatments, and treatments that have very

different implications for patients (e.g., surgery vs. long-term medication). Where trial treatments are readily available outside the trial and patients know that they can have a preferred treatment if they decline to participate in a trial, the results of an RCT are likely to be similar to the results obtained from the randomized subgroups of a PRPT. However, the PRPT provides the opportunity to study the outcomes in patients who have strong preferences and are given their preferred treatment as well as studying patients in equipoise. Where a new treatment is only available within a trial and patients participate in the hope of having the new treatment, the results of an RCT are likely to be distorted by disappointment effects that can be avoided by using a properly implemented PRPT design.

PARTICIPANTS

In the context of research, participants are individuals who are selected to participate in a research study or who have volunteered to participate in a research study. They are one of the major units of analysis in both qualitative and quantitative studies and are selected using either probability or nonprobability sampling techniques. Participants make major contributions to research in many disciplines. The manner in which their contributions are made is determined by the research design for the particular study and can include methodologies such as survey research, experiments, focus groups, and naturalistic observation. This entry focuses on the selection and protection of participants.

Participant Selection and Recruitment

In research literature, the word *participants* is used often interchangeably with *informants*, *respondents*, *subjects*, or *interviewees*. However, there are some contextual distinctions between these terms. In survey research, participants are often referred to as respondents/interviewees. Respondents/interviewees provide information about themselves (e.g., opinions, preferences, values, ideas, behaviors, experiences) for data analysis by responding through self-administered surveys or interviews (e.g., telephone, face-to-face, email, fax). When experiments are being conducted, *subjects* are the preferred term for participants. Subjects are usually studied in order to gather data for the study. Finally, participants are considered to be informants when they are well versed in the social phenomenon of study (e.g., customs, native language) and are willing to speak about it. Overall, the distinction between a respondent and an informant is of particular importance because all respondents can talk about themselves; however, not all respondents can be good informants.

Participants can be identified/selected using two methods—probability sampling or nonprobability sampling. The method used for sample selection is dictated by the research questions. In probability sampling methodologies (e.g., simple random, systematic, stratified random, cluster), a random selection procedure is used to ensure that no systematic bias occurs in the selection process. This contrasts with nonprobability sampling methodologies (e.g., convenience, purposive, snowball, quota), where random selection is not used.

Once potential participants are identified, the next task involves approaching the individuals to try to elicit their cooperation. Depending on the purpose of the research, the unit of analysis may be either individuals or groups. For example, if a researcher is examining

student achievement based on test scores across two Primary 1 classes at School X, the unit of analysis is the student. In contrast, if the researcher is comparing classroom performance, the unit of analysis is the class because the average test score is being used.

The manner in which cooperation is elicited will vary according to the technique used to collect the data. However, the procedure generally involves greeting the participants, explaining the purpose of the study and how participants were selected, assuring participants that their responses will remain anonymous/confidential and that data will be aggregated prior to reporting, and asking them to participate. In other words, the actual recruitment involves giving participants sufficient information to enable them to give free and informed consent without being coerced. Participants must also be assured that they have the right to withdraw at any time.

In group situations (e.g., focus groups, classroom surveys) where potential participants are all in one location, cooperation may not be much of a problem. However, when random sampling is used and the unit of analysis is the individual, cooperation may be more difficult. For example, in telephone interviews, many potential participants may simply hang up the phone on telephone interviewers, and mail surveys may end up in the trash as soon as they are received. With face-to-face interviews, interviewer characteristics such as social skills and demeanor are partially important in trying to elicit cooperation. In general, the response rate for face-to-face interviews is higher compared to other methods, perhaps because participants may feel embarrassed to close the door in the interviewer's face. When face-to-face interviews are being conducted, a letter is generally sent in advance to establish the legitimacy of the study and to schedule an appointment. However, when data are being collected nationwide (e.g., national census), public announcements on the radio/television and in local newspapers is the preferred route.

In research where participants have volunteered to participate (e.g., medical studies), cooperation is not an issue. However, other issues may take center stage. For example, all recruitment materials (e.g., press releases, radio/television/newspaper advertisements, flyers, posters) have to be approved by an institutional review board prior to publicity to ensure that eligibility criteria are clear; selection criteria are fair (i.e., some groups are not favored over others); advertising content is accurate/appropriate (e.g., if a study is comparing a new drug to a placebo, it must state that some participants will receive the placebo); benefits to participants are clear; any expected harm to participants (e.g., pain, distress) is outlined; and so on.

Protection of Participants

In general, most research involving humans requires the approval of an institutional review board (IRB) to ensure that researchers are not violating the basic ethical rights of humans and/or causing harm to participants. The principles for ethical research are outlined in the "Belmont Report—Ethical Principles and Guidelines for the Protection of Human Subjects of Research." Of particular importance is research involving medical studies and research involving the use of children, the elderly, or persons who are mentally incompetent or have an impaired decision-making capacity. Research involving these types of participants is generally scrutinized in great detail by IRBs, so researchers have to provide very detailed protocol to the IRB in order to obtain approval. For the conduct of these types of research, consent may often need to be obtained from a third party. For example, in research involving children, parental/guardian consent must be obtained.

Although consent is a prerequisite for most types of research, there are some instances where it may not be desirable or possible. For example, in naturalistic observation, consent is not desirable because of the issue of reactivity, namely, where participants change their behavior when they are aware that they are being observed. In such research, it is incumbent that the researcher be mindful of the ethical principles as outlined in the Belmont Report and respect people's privacy and dignity.

PATH ANALYSIS

Path analysis is a way to examine chains and networks of correlated variables. The use of path analysis to examine causal structures among continuous variables was pioneered by Sewall Wright and popularized in the social sciences through the work of Peter M. Blau and Otis D. Duncan, among others. There are several advantages to path analysis that account for its continuing popularity: (a) It provides a graphical representation of a set of algebraic relationships among variables that concisely and visually summarizes those relationships; (b) it allows researchers to not only examine the direct impact of a predictor on a dependent variable but also see other types of relationships, including indirect and spurious relationships; (c) it indicates, at a glance, which predictors appear to have stronger, weaker, or no relationships with the dependent variable; (d) it allows researchers to decompose or split up the variance in a dependent variable into explained and unexplained and also allows researchers to decompose the explained variance into variance explained by different variables; and (e) it allows researchers to decompose the correlation between a predictor and a dependent variable into direct, indirect, and spurious effects. Path analysis is used to describe systems of predictive or, more often, causal relationships involving three or more interrelated variables. Because path analysis is most often used in causal rather than purely predictive analysis, the language of causality is adopted here, but it should be borne in mind that causal relationships require more than path analysis for evidence; in particular, questions not only of association and spuriousness but also of causal (and thus implicitly temporal) order must be considered.

In path analysis, multiple regression models are combined, so more than one variable is typically treated as a dependent variable with respect to other variables in the model. Variables that affect other variables in the model, but are not affected by other variables in the model, are called *exogenous* variables, implying not so much that they are outside the model but that their explanation lies outside the model. A variable that is affected or predicted by at least one of the other variables in the model is considered an *endogenous* variable. An endogenous variable may be the last variable in the causal chain, or it may be an *intervening* variable, one that occurs between an exogenous variable and another endogenous variable. In practice, in any path analytical model, there will be at least one exogenous and one endogenous variable.

The simple patterns of direct, indirect, and spurious relationships are diagrammed in Figure 1. Diagram A in Figure 1 shows a simple relationship in which X and

Y are both exogenous variables, and each has a direct effect on the endogenous variable Z. Diagram B in Figure 1 shows a spurious relationship, in which X is an exogenous variable, Y and Z are endogenous variables, and X has an effect on both Y and Z. From Diagram B, we would expect that the zero-order correlation between Y and Z would be nonzero, but that the partial correlation between Y and Z, controlling for X, would be zero. Diagram C in Figure 1 shows a causal chain in which X is an exogenous variable and has a direct effect on Y but not on Z, Y and Z are endogenous variables, and Y has a direct effect on Z. In Diagram C, X has an indirect effect on Z through its effect on Y. We would therefore expect the zero-order correlation between X and Z to be nonzero, but the partial correlation between X and Z, controlling for Y, to be zero. Diagram D in Figure 1 shows a mixture of direct and indirect effects and incorporates all of the effects in the previous three diagrams. X is an exogenous variable that has a direct effect on the endogenous variable Y, a direct effect on the endogenous variable Z, and an indirect effect (via Y) on the endogenous variable Z. Y is an endogenous variable that is related to Z in part through a direct effect but also in part through a spurious effect because X is a cause of both Y and Z. In this diagram, we would expect the zero-order correlations among all the variables to be nonzero, the partial correlation between X and Z controlling for Y to be nonzero but smaller than the zero-order correlation between X and Z (because part of the zero-order correlation would reflect the indirect effect of X on Z via Y), and the partial correlation between Y and Z controlling for X to be nonzero but smaller than the zero-order correlation between Y and Z (because the zero-order correlation would reflect the spurious relationship between Y and Z resulting from their both being influenced by X).

Figure 1 Examples of Causal Relationships

Note. (a) Direct effects of X and Y on Z. (b) Spurious effect of X on Y and Z. (c) Causal chain from X to Y to Z. (d) Direct plus indirect effects.

Diagrams A and B in Figure 1 both represent models that can be described as *weakly ordered recursive* models. If we trace each arrow forward, we never come back to the variable where we started, but there are two variables (X and Y in Diagram A, Y and Z in Diagram B) between which there is not a clear causal ordering. In Diagram A, X and Y occur before Z , but it is not evident from the diagram that either occurs before the other. Similarly in Diagram B, Y and Z both occur after X , but there is no clear ordering between Y and Z . Diagrams C and D represent *strongly recursive* or *fully ordered recursive* models, in which it is again the case that if we trace each arrow forward, we never come back to the variable where we started, but it is also the case that X is the only exogenous variable in the model, and there is a clear ordering from left to right, with no ambiguity about which variable comes before or after any other variable. It is also possible to have *nonrecursive* models, in which it is possible to start from at least one variable, trace the arrows forward, and come back to the variable where you started. For example, in Diagram B in Figure 1, if we added two arrows, one from Y to Z and another from Z to Y , we would have a nonrecursive model, with a *nonrecursive loop* between Y and Z . Alternatively, in Diagram D in Figure 1, if we reversed the direction of the arrow from X to Z , so it pointed instead from Z to X , we would have a nonrecursive loop involving all three of the variables (from X to Y to Z and back to X again).

Decomposition of Variance in Path Analysis

In a model with three or more variables, X , Y , and Z , where X and Y are predictors of the dependent variable Z (corresponding to Diagram A in Figure 1), there may be (a) shared variance between X and Y that is not shared with Z ; (b) shared variance between X and Z that is not shared with Y ; (c) shared variance between Y and Z that is not shared with X ; and (d) shared variance among all three variables, X , Y , and Z . The shared variance between X and Y that is not shared with Z represents the *zero-order covariance* between X and Y , and if expressed as a correlation instead of a covariance, it is the zero-order correlation between X and Y , the two exogenous variables in Diagram A of Figure 1. *Zero order* means that there are no (zero) other variables being statistically controlled in the computation of this correlation. The shared variance between X and Z that is not shared with Y , expressed as a correlation, is the *first-order partial correlation between X and Z , controlling for Y* , $r_{ZX \cdot Y}$. *First order* means that one variable (Y) is being controlled when calculating this

measure of the association between X and Z . This partial correlation, if squared ($r_{ZX \cdot Y}^2$), may also be described as the variance in Z uniquely attributable to X . Similarly, the shared variance between Y and Z that is not shared with X is the first-order correlation between Y and Z controlling for X , $r_{ZY \cdot X}$. This partial correlation, if squared ($r_{ZY \cdot X}^2$), may also be Y . Finally, the variation shared among all three variables can be thought of as the joint effect of X and Y on Z , or the extent to which the effect of one exogenous variable on Z is confounded by (or not clearly distinguishable from) the effect of the other exogenous variable.

If X and Y are uncorrelated, the variation shared by all three variables is zero, and the partial correlation of each exogenous variable with the dependent variable is the same as the zero-order correlation. In the more usual case when X and Y are correlated with each other, the variation shared by all three variables has traditionally been treated in two different ways. In analysis of variance and partial correlation analysis, it is attributed to neither X nor Y , but treated as a separate source of explained variance in Z . In some standard analysis of variance output, the variance scenarios noted earlier in (b), (c), and (d) would each be presented as separate sources of explained variation in Z . In regression analysis, (d) is partitioned between X and Y , and more of (d) will be attributed to whichever of X and Y has the higher overall (zero-order) correlation with Z . Unless X and Y provide a perfect prediction of Z , there will be variance in Z not shared with X and Y . The proportion of the total variance in Z explained by X and Y is equal to the squared multiple correlation of Z with X and Y , or R^2 . The variance in Z that is not explained by X and Y (separately or in combination) is the unexplained variance (actually, the unexplained proportion of the variance), which can be written as $1 - R^2$, the square root of which, $\sqrt{1 - R^2}$, is sometimes explicitly included in a path model as the path coefficient for the *residual* effect, the presumed effect of variables not in the model that, if included, would explain the endogenous variable perfectly.

Path analysis, which is based on multiple linear regression analysis, like regression analysis partitions all of the explained variance in Z among the predictors. According to this method of partitioning the variance, the proportion of the variance in Z that is estimated to be shared directly (but not uniquely because we are splitting up shared explained variance among the predictors) is equal to the product of the standardized regression coefficient and the zero-order correlation between the dependent variable and the predictor (e.g., $r_{ZX}b_{ZX}^*$ or $r_{ZY}b_{ZY}^*$). The sum of the products of all the standardized path coefficients and their associated zero-order correlations is known to be equal to the

total proportion of the variance that is explained or R^2 , that is, $\Sigma(b^*)(r) = R^2$. In this sense, the explained variance can be partitioned completely, but again not uniquely, among the predictors in the model, without specific reference to a separate shared effect.

Methods of Estimating Path Coefficients

Methods of estimating path coefficients include (a) simultaneous estimation using structural equation modeling software, (b) separate estimation using ordinary least squares regression software when all variables in the model are (or can be treated as though they were) measured on an interval or ratio scale of measurement, and (c) separate estimation using logistic regression (and possibly ordinary least squares) when at least some of the variables in the model are dichotomous or categorical variables. In the earlier years of path analysis, the usual method of calculating path coefficients was to run separate regression analyses on each of the endogenous variables in the model. Scott Menard describes an approach to constructing path models using logistic regression analysis for categorical (dichotomous, nominal, or ordinal) variables that also relies on separate estimation, in which the categorical variables are treated as inherently categorical, rather than assuming that they are manifest indicators of latent (not directly measured, but estimated on the basis of observed indicator variables in the model) continuous variables.

When all of the variables in the model can be either (a) measured on a truly interval or ratio scale or (b) justifiably assumed to be categorical manifest indicators of continuous latent variables, the accepted practice has shifted to the use of software that simultaneously estimates all of the relationships in the model. The term *structural equation modeling* has come to refer less to the model itself than to the more sophisticated techniques for estimating simultaneous equation causal models. As described by David Heise, one major advantage of full-information maximum likelihood simultaneous equation methods for estimating path models is that they make more efficient use of valid theory, incorporating all such knowledge into the estimate of each system parameter, resulting in more precise estimates. The major disadvantage, correspondingly, is that they similarly incorporate any erroneous theory into the calculations, so if part of the model has been misspecified, all coefficient estimates may be affected instead of just a few. In general, Heise recommends the use of full-information methods in the latter stages of research, when there is a high level of confidence in the specification of the model. Estimation of a single equation at a time may be more appropriate in the earlier stages of

model testing, when the emphasis is less on precise estimation of coefficients for causal paths that are known with some certainty to belong in the model than on deciding *which* causal paths really belong in or are important to the model.

Decomposition of Zero-Order Correlations in Path Analysis

Figure 2 presents the model from Diagram D of Figure 1 with coefficients assigned to each of the causal paths. One approach to calculating the coefficients for path analysis models is to first regress the last variable in the causal order (Z) on the prior two variables, then to regress each endogenous variable in turn, from last to second last, on the variables that precede it in the model. In this approach, the path coefficients (the numbers associated with each of the arrows) are identically the standardized regression coefficients produced by ordinary least squares regression analysis. In the model in Figure 2, X has a direct effect (a path coefficient or standardized regression coefficient) on Z is .200, a direct effect on Y is .100, and the direct effect of Y on Z is .300. The *indirect* effect of X on Z can be found by multiplying the path coefficients that connect X to Z via other variables. In this simple model, there is only one such path, and the indirect effect of X on Z is equal to $(b^*_{XY})(b^*_{YZ}) = (.100)(.300) = .030$. Alternatively, one can follow the common practice of using “p” in place of “b*” to designate the path coefficients and rewrite this as $(p_{XY})(p_{YZ}) = .030$. The *total* effect of X on Z is equal to the *direct* effect plus the sum of all the *indirect* effects (of which there is only one in this example): $(p_{ZX}) + (p_{XY}p_{YZ}) = (.200) + (.100)(.300) = .230$.

The fundamental theorem of path analysis states that the correlation between any pair of variables, such as X and Z or Y and Z, can be expressed as the sum of

Figure 2 Path Models and Decomposition of Correlations

Note. $r_{ZX} = .230$.

all the nonredundant paths between the two variables. For a fully ordered recursive model, this is the sum of the direct plus indirect plus spurious causal paths between the two variables (i.e., the total effect plus the sum of the spurious effects) when the path coefficients are expressed as standardized regression coefficients. For a weakly ordered recursive model, this may also include paths involving correlations between exogenous variables, as described, for example, by Herbert B. Asher. It must also be the case that all nonzero paths are included in the model. When some paths are defined to be zero a priori, one test of how well the model works is to compare the *observed* correlation with the *implied* correlation (the latter calculated based on the path coefficients) between each of the predictors and the endogenous variables.

The total effect of X on Z in the present example will be equal to the zero-order correlation between X and Z . Because Y has no indirect effect on Z , the direct effect of Y on Z is the same as the total effect, .300, but there is also a spurious effect, equal to the product of the path from X to Y and the path from X to Z : $(.100)(.200) = .020$, implying a zero-order correlation between Y and Z of $(.300) + (.020) = .320$. Finally, the only relationship between X and Y is the direct effect of X on Y , and the zero-order correlation in this instance should be equal to the path coefficient for that direct effect, .100. Because the path coefficients in Figure 2 are standardized regression coefficients, it is reasonable to conclude that the impact (measured in terms of the total effect) of Y on Z is stronger than the impact of X on Z , even when we include direct as well as indirect effects.

Now consider some possible changes in the model. If the path coefficient between X and Z were .280 instead of .200, then the total effect of X on Z would be $(.280) + (.030) = .310$, and the total effect of X on Z (.310) would be slightly larger than the total effect of Y on Z (.300), even though the zero-order correlation between Y and Z (.320, equal to the direct plus spurious effect) is larger than the zero-order correlation between X and Z (.310, equal to the direct plus indirect effect). Second, if the direct effect of X on Z were zero instead of .200, X would still have the indirect effect, .030, on Z , and because it had only an indirect effect, the indirect effect would be equal to the total effect (and to the zero-order correlation) between Z and X . Third, if the direct effect of X on Y were zero, then the direct effect of X on Z would be equal to the total effect of X on Z , .200, and moreover, with X and Y uncorrelated, the path coefficients would be equal not only to the standardized regression coefficients but also to the zero-order correlations for the relationship between X and Z and the relationship between Y and

Z . All of these are relatively simple examples. In general, it will not usually be the case that the zero-order correlation coefficient will be equal to the standardized regression coefficient, that predictors will be completely uncorrelated, or that total effects will be equal to either the direct or the indirect effect.

PEARSON PRODUCT-MOMENT CORRELATION COEFFICIENT

In the late 19th century, Sir Francis Galton was measuring many different biological and sociological variables and describing their distributions using the extant methods for single variables. However, there was no way to quantify the degree of relationship between two variables. The Pearson product-moment correlation coefficient (hereafter referred to as “coefficient”) was created by Karl Pearson in 1896 to address this need. The coefficient is one of the most frequently employed statistical methods in the social and behavioral sciences and is frequently used in theory testing, instrument validation, reliability estimation, and many other descriptive and inferential procedures.

This entry begins by defining the coefficient and describing its statistical properties. Next, this entry

discusses descriptive and inferential procedures. It closes with a discussion of the coefficient's limitations and precautions for interpreting.

Definition

The population coefficient, which is typically abbreviated as ρ , or the Greek letter rho, is an index of the degree and direction of linear association between two continuous variables. These variables are usually denoted as X (commonly labeled as a predictor variable) and Y (commonly labeled as an outcome variable). Note, however, that the letters are arbitrary; the roles of the variables implied by these labels are irrelevant because the coefficient is a symmetric measure and takes on the same value no matter how two variables are declared.

The population value is estimated by calculating a sample coefficient, which is denoted by β "rho hat," or r . The sample coefficient is a descriptive statistic; however, inferential methods can be applied to estimate the population value of the coefficient.

Statistical Properties of the Coefficient

The coefficient can take on values between -1 and 1 (i.e., $-1 \leq \rho \leq 1$). The absolute value of the coefficient denotes the strength of the linear association $|\rho| = 1$ indicating a perfect linear association and $\rho = 0$ indicating no linear association. The sign of the coefficient indicates the direction of the linear association. When high scores on X correspond to high scores on Y and low scores on X correspond to low scores on Y , the association is positive. When high scores on X correspond to low scores on Y , and vice versa, the association is negative.

Bivariate scatterplots are often used to visually inspect the degree of linear association between two variables. Figure 1 demonstrates how an (X, Y) scatterplot might look when the population correlation between X and Y is negligible (e.g., $\rho = .02$). Note that there is no observable pattern in the dots; they appear to be randomly spaced on the plot.

Figure 2 demonstrates how an (X, Y) scatterplot might look when $\rho = .90$. There is an obvious pattern in the paired score points. That is, increases in X are associated with linear increases in Y , at least on average.

Figure 3 demonstrates how an (X, Y) scatterplot might look when $\rho = -.30$. In this plot, increases in X are associated with linear decreases in Y , at least on average. Due to the lower absolute value of the coefficient in this case, the pattern is not as easily identifiable.

Shared Variance

In addition to the strength and direction of linear association, the coefficient also provides a measure of the shared variance between X and Y , which is calculated by squaring the coefficient. The resulting value, r^2 , is also referred to as the *coefficient of determination*. Specifically, r^2 indicates the percentage of variance in one variable that is attributable to the variance in the other variable. For example, if the correlation between X and Y is $\rho = .90$, then $r^2 = .81$; therefore, 81% of the variance in X scores can be predicted from the variance in Y scores.

Descriptive Procedures for r

Suitability of r

The appropriateness of computing r is based on the assumption that X and Y are both continuous variables (i.e., X and Y are measured on either interval or ratio scales) and that the relationship between X and Y can be best represented by a linear function. It is possible for two variables to have a linear or nonlinear form of relationship; however, the coefficient only quantifies the direction and degree of linear relationship between two variables. If the association between X and Y is curvilinear, the coefficient can still be computed but does not provide the optimal representation of the relationship. In the case of a nonlinear monotonic relationship, Spearman's correlation coefficient is a better measure of the degree of monotonic association between X and Y . Incidentally, Spearman's correlation coefficient is mathematically the same as computing Pearson's correlation coefficient on the ranks of the data.

Figure 1 No Correlation

**Figure 2** Strong Positive Correlation**Figure 3** Moderate Negative Correlation

Calculating the Value of r

The coefficient provides an index of the consistency with which scores on X are linearly associated with scores on Y . If scores on X are linearly associated with scores on Y , then the location of an individual's score in the X distribution (i.e., his or her standardized z score on X) will be similar to (or opposite of, in the case of an inverse relationship) the location of the individual's score in the Y distribution (i.e., his or her standardized z score on Y). Therefore, the coefficient is calculated by finding the average cross-product of the z scores of X and Y :

$$\rho = \frac{\sum_{i=1}^N Z_X Z_Y}{N} \text{ in the population and}$$

$$r = \frac{\sum_{i=1}^n z_X z_Y}{n-1} \text{ in the sample,}$$

where Z_X , Z_Y , z_X and z_Y are the z scores for X and Y in the population and sample, respectively, and N and n are the population and sample sizes, respectively. This formula can also be re-expressed as the ratio of the covariance of X and Y to the product of the standard deviations of X and Y ; in other words, it can be expressed as the ratio of how much X and Y vary together compared to how much X and Y vary separately:

$$\rho = \frac{\text{Cov}(X, Y)}{SD(X)SD(Y)},$$

where SD denotes standard deviation.

Inferential Procedures for θ Using r

Calculating Confidence Intervals for θ Using r

It is possible to calculate a confidence interval for ρ using the value of the sample coefficient r . However, to achieve proper confidence coverage, the value of r has to be transformed using what is known as Fisher's z transformation, here denoted, z'

$$z' = \frac{1}{2} \left[\ln \left(\frac{1+r}{1-r} \right) \right].$$

where $\ln$ is the natural logarithm. Because the asymptotic sampling distribution for Fisher's z values is known to be the normal distribution with standard error

$$SE = \frac{1}{\sqrt{n-3}},$$

a confidence interval for ρ on the transformed scale can be constructed in the prototypical manner via

$$z' \pm \text{TLV} \cdot \frac{1}{\sqrt{n-3}},$$

where TLV is the table-look-up value associated with the desired confidence level of the interval (e.g., $\text{TLV}_{95\%} = 1.96$, $\text{TLV}_{90\%} = 1.65$). Once the confidence interval for the value of ρ on Fisher's z scale has been constructed, these bounds of the confidence interval must be transformed back into bounds for the confidence interval for ρ by using

$$\rho_{\text{Lower}} = \frac{\exp(2 \cdot z'_{\text{Lower}}) - 1}{\exp(2 \cdot z'_{\text{Lower}}) + 1} \text{ and}$$

$$\rho_{\text{Upper}} = \frac{\exp(2 \cdot z'_{\text{Upper}}) - 1}{\exp(2 \cdot z'_{\text{Upper}}) + 1},$$

where z'_{Lower} and z'_{Upper} are the confidence bounds of the confidence interval for ρ on Fisher's z scale.

Testing $H_0 : \theta = 0$

To test the null hypothesis that the population correlation between X and Y is 0 (i.e., to test $H_0 : \rho = 0$ vs. $H_1 : \rho \neq 0$), one can use the t -distribution by calculating a t score for r using

$$t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}},$$

where r is the calculated correlation coefficient,

$$\frac{\sqrt{1-r^2}}{\sqrt{n-2}}$$

is the standard error of r , and n is the sample size. One then compares this calculated t value to a critical t value with $df = n - 2$ at a desired alpha level. In addition, most statistical textbooks provide lookup tables in which to locate critical values for r without having to convert r to a t score.

Testing a Nonzero Null Hypothesis

Researchers may want to test a null hypothesis other than $H_0 : \rho = 0$ to determine if a calculated coefficient is significantly different from some other value, for example, .20 (i.e., they may want to test $H_0 : \rho = .20$ vs. $H_1 : \rho \neq .20$). To do this, the researcher must convert both the calculated and critical values of r to a z score using Fisher's z transformation and then use the prototypical formula for a test statistic to conduct the test:

$$\text{Test Statistic} = \frac{z'_{(\text{calculated})} - z'_{(\text{hypothesized})}}{\frac{1}{\sqrt{n-3}}},$$

where $z'_{(\text{calculated})}$ is the z -transformed r value calculated from sample data, $z'_{(\text{hypothesized})}$ is the z -transformed value hypothesized under the null, and the expression in the denominator is the standard error of r on Fisher's z scale.

Testing for a Difference Between Two Independent Correlations

One can also test to determine if two independent correlations are significantly different by calculating a z score of the difference between the z transformed correlations in an analogous manner:

$$\text{Test Statistic} = \frac{z'_{\text{Sample 1}} - z'_{\text{Sample 2}}}{\frac{1}{\sqrt{(n_1 - 3) + (n_2 - 3)}}},$$

where $z'_{\text{Sample 1}}$ and $z'_{\text{Sample 2}}$ are the z -transformed correlation coefficients for Sample 1 and Sample 2, respectively, and n_1 and n_2 are the sample sizes for Samples 1 and 2, respectively.

Assumptions for Inferential Procedures

The correctness of the inferential procedures in the preceding section is based on the following set of assumptions that have to hold in addition to the two variables being continuous and the relationship being linear as stated earlier.

1. *The scores of X and Y are sampled from a bivariate normal distribution.* Bivariate normality refers to the condition in which all individuals' Y scores are normally distributed in the population across all X scores. That is, if one examined the Y scores of all individuals with an X score of, for example, 50, one should find that, assuming bivariate normality holds, these individuals' Y scores are normally distributed. Essentially, bivariate normality is obtained when both variables are normally distributed. When one or both variables are skewed, bivariate normality is often violated, possibly adversely affecting the inferential properties of the coefficient.
2. *Homoscedasticity.* Homoscedasticity refers to the condition in which, for all given X values, the amount of variation in Y values remains relatively constant. Homoscedasticity would be violated if, for example, at the lower end of the X scale, there was very little variation in Y scores, but at the upper end of the X scale, there was a large amount of variation in the Y scores.
3. *The sample of scores has been randomly selected from the population of interest.* If the sample is not randomly selected, it is uncertain to what degree the calculated coefficient represents the population value, because the calculated value may be systematically biased upward or downward.

Limitations of the Coefficient and Precautions Regarding Its Interpretation**Outliers**

The value of the coefficient is quite susceptible to outliers. The presence of even one outlier can spuriously attenuate or inflate the true value of the correlation. Therefore, it is necessary to attempt detection of outliers when wishing to draw conclusions based on a calculated coefficient.

Restriction of Range

In addition to outliers, restriction of range can have unwanted effects on the value of the coefficient. That is, when only a portion of the entire range of values of a variable is included in the sample (i.e., if the sample data are not representative of the population data), the calculated coefficient may be an inaccurate estimate of the population value. Therefore, one must be careful to consider the range of possible values of the X and Y variables and to take into account to what degree that range is represented in one's current sample.

Correlation and Causation

It is important to emphasize that although a correlation coefficient may suggest that two variables are associated, it does not prove any causal relationship between the two variables. Researchers must be careful about conclusions drawn from correlation coefficients; even when $r = 1.00$, one cannot be sure that one variable *causes* another, only that one variable is *related* to another.

PEER EFFECTS

The term *peer effects* refers to the inclination of an individual to behave similarly to the behavior of a reference group to which the individual herself

belongs. Communication and social interactions with peers, that is, members of the reference group, affect individual behavior, for better and for worse. In the workplace, the productivity of a worker varies depending on the productivity of her coworkers. If a worker's productivity falls behind her coworkers' productivity, he may exert more effort to acquire new skills by learning from them. However, in prisons for example, interaction with peers may have adverse effects, if inmates build criminal capital by learning from one another.

Individuals also rely on their peers as a source of information. A mother takes information from her neighborhood and family peers about the advantages and disadvantages of working particular hours. Moreover, peers could shape others' choices and preferences. Seeing friends engage in risky behaviors could induce a desire for those behaviors. With regard to complicated financial decisions, individuals may simply mimic the behavior of others. People's decisions on major purchases, such as real estate or a car, often are similar to the choices of their peers. The effects on students of their peers in the classroom and at school have received attention from social scientists and policymakers, particularly since the 1990s. This entry first discusses peer effects in education, then describes empirical approaches used to estimate peer effects.

Peer Effects in Education

In education, peer effects present intriguing possibilities and need to be further explored. The constantly growing number of studies on peer effects in education illustrates the importance of the topic in education policies, such as school choice programs and within-school tracking. If we think of students as being affected by the adults around them, we can also think of them as being influenced by their peers. One example of a direct effect could be classmates teaching one another. Furthermore, classmates can affect their peers through knowledge spillovers and through their influence on academic and disciplinary standards in the classroom. Peer effects refer to externalities in which the actions or characteristics of a reference group affect an individual's behavior or outcomes. This is not to say that peers are exclusively responsible for an individual's behavior or outcomes, but they do play an important role.

Students' achievement is linked to the average ability of their peers. Yet peer effects may also stem from peers' characteristics. To estimate peer effects in education, the vast majority of studies define peer groups at the classroom or school level and regress individual

outcomes on the group mean outcomes and the group mean of demographic and socioeconomic characteristics. The outcomes range from schooling achievement, like school test performance, to behavioral outcomes, such as classroom disruption and violence. Some studies solely examine the effect of peers' characteristics because the makeup or composition of a classroom, such as the average parents' education level, the average family income, the number of children with disabilities, racial diversity, and gender balance, can create peer effects. For example, students with designated disabilities may draw disproportionately on their teacher's time, or higher parents' education level may put more pressure on teachers to hold higher learning expectations for their students or affect how educators react to their students.

Empirical Approaches in Estimating Peer Effects

The literature on peer effects varies widely in empirical approaches because identifying peer effects remains challenging, and various specifications are used to isolate peer effects. In his 1993 pioneering work, Charles F. Manski distinguishes between three types of social interactions that are relevant to the study of peer effects in education: exogenous (contextual), endogenous, and correlated effects. Exogenous effects arise when peer characteristics influence students' learning outcomes, endogenous effects are the effects of peers' abilities and learning outcomes, and correlated effects arise because peers are subject to a common environment. Manski argues that, in the absence of randomly assigning students and teachers to schools and classrooms, it is hard to separate exogenous and endogenous effects from correlated effects. Children self-select into schools based on their parental residential choices and parental educational preferences. Accordingly, the common environment of schools reflects students' family background.

To overcome the self-selection issue, some studies exploit random assignment experiments and quasi-random natural experiments. For instance, in their 2006 study, Julie Berry Cullen and her colleagues use randomized lotteries that determine high school admission in the Chicago Public Schools to estimate the effects of attending high schools with higher achieving peers. In the absence of random assignment, the primary approach to deal with the self-selection issue is to exploit variation within schools across time, assuming that this variation is as good as random.

Manski also shows that, even in the absence of correlated effects, another challenge in estimating peer effects is the reflection problem: the simultaneity

between a student's impact on her peers' outcomes and her peers' impact on the student's outcome. Studies in peer effects usually neglect the reflection issue due to the difficulties in addressing this issue. Recently, a burgeoning literature explores how to exploit partially overlapping peer groups to overcome the reflection problem. Each individual interacts with different peer groups, such as friends, classmates, neighbors, relatives, and coworkers, that may partially overlap. This literature proposes to use peers of peers as an instrument to explain peers' characteristics. An example may help us understand the intuition behind the proposed approach. Suppose we are interested in estimating the effects of teenagers' schoolmates on the propensity to smoke cigarettes. A teenager interacts with neighborhood peers as well as schoolmates, yet only some neighborhood peers may attend the same school as the teenager. Those neighborhood peers who attend other schools, the so-called excluded peers, do not affect the teenager's schoolmates directly but only indirectly through affecting the teenager's smoking behavior. The excluded peers of schoolmates are, thus, used as an instrument for schoolmates' smoking behavior.

To overcome these empirical challenges, experimental studies such as intervention studies are important and can avoid the self-selection problem. Such experiments are rarely conducted in the education context, however, as they would require students to be randomly assigned to schools and classrooms. Given that such an approach is ethically questionable, quasi-experimental designs remain the methodological instrument of choice. Besides, interview studies offer the possibility to explore why people behave in a certain way. As peers' influence clearly plays a significant role in our everyday life, further studies, which provide reliable data and thus practical implications, are needed.

PERCENTILE RANK

There is no standard definition of a percentile, but three common definitions yield similar, if not identical, results when working with a large sample size. Some define a percentile to be the smallest value that a specified percentage of the observations is less than. Another definition is that a percentile is the smallest value that a specified percentage of the observations is less than or equal to, and this is commonly what is referred to as the percentile rank. Conveniently, a third definition that uses both of the previous two exists and handles small data sets consistently. This third method is recommended by the National Institute of Standards and Technology (NIST) for identifying percentiles and is used here.

Calculation

Notation

$Y(p)$	the p th percentile
n	the sample size, or the number of observations
r	the rank, or position in an ordered list, of an observation
$Y_{(r)}$	the observation with rank r in the sample (e.g., $Y_{(1)}$ is the smallest observation; $Y_{(n)}$ is the largest)
p	the percentage of interest

Formula

First, sort all n raw scores in ascending order. Next, find the rank (r), or position in the ordered listing of scores, of the percentile of interest (p):

$$r = \frac{p}{100}(n + 1)$$

To find the score representing that percentile, $Y(p)$,

$$Y(p) = \begin{cases} Y_{(1)} & k = 0 \\ Y_{(n)} & k = n \\ Y_{(k)} + d(Y_{(k+1)} - Y_{(k)}) & 0 < k < n, \end{cases}$$

where k is the integer portion of r , and d is the decimal portion of r , such that $k + d = r$.

Example

The raw scores of a test administered to seven people are listed below, along with their respective ranks. You are interested in finding the 80th percentile.

Score	Rank
85	4
77	1
88	5
91	7
90	6
81	2
83	3

The rank, r , of the 80th percentile is

$$r = \frac{p}{100}(n + 1) = \left(\frac{80}{100}\right)(7 + 1) = 6.4.$$

Using the definitions above, $k = 6$ and $d = 0.4$, giving $k + d = r$. The 80th percentile can now be calculated as follows:

$$\begin{aligned} Y(80) &= Y_{(k)} + d(Y_{(k+1)} - Y_{(k)}) \\ &= Y_{(6)} + d(Y_{(7)} - Y_{(6)}) = 90 + .4(91 - 90) \\ &= 90.4. \end{aligned}$$

That is, an examinee who received a raw score of 90.4 on this exam performed as well as or better than 80% of the other test takers. For a sample size of only seven people, one can see that this is neither very informative nor useful. However, when dealing with larger samples, percentiles can be very helpful in describing where one stands in relation to others.

The Sample Median

The sample median is a useful statistic in that, unlike the mean and mode of a set of observations, it is unaffected by outliers and skewness in the data because it

depends only on the values in the very middle of all the observations. The median is often used to report statistics whose distributions are widely varied or skewed, such as annual household income for a community or the ages of students enrolled in a program.

By definition, the median is the halfway point of a data set: Exactly half of the observations are less than it, and therefore, exactly half are greater than it. Thus, the median is also the 50th percentile of a set of data.

Example

One can see that, if r is an integer, no interpolation is necessary, and the percentile is the value with rank r . An example illustrates this point by finding the 50th percentile, or median, of the seven scores above.

$$r = \frac{p}{100}(n+1) = \left(\frac{50}{100}\right)(7+1) = 4.0$$

Now, $k = 4$ and $d = 0.0$. To find the median,

$$\begin{aligned} Y(50) &= Y_{(k)} + d(Y_{(k+1)} - Y_{(k)}) \\ &= Y_{(4)} + d(Y_{(5)} - Y_{(4)}) = 85 + 0(88 - 85) \\ &= 85. \end{aligned}$$

Thus, exactly half of the seven test scores are below 85, and the other half are greater than 85.

Other Special Cases

In addition to the median, other special cases of percentiles are often used to classify students, schools, or others. Besides the median, the most commonly used percentiles are the first and third quartiles. As their name suggests, quartiles divide a data set into fourths. That is, the first quartile (denoted Q_1) signifies the value with one quarter of the data less than or equal to it; the third quartile (Q_3) is the value with three quarters of the data less than or equal to it. Therefore, to find the first quartile of a data set, one need only find the 25th percentile. Similarly, finding the third quartile is the same as finding the 75th percentile. The median is the second quartile (Q_2).

Another, less common, special case of percentiles are deciles, which divide the data into tenths. They can likewise be found using the formula above. The first example, finding the 80th percentile, was also an example of finding the eighth decile of the exams.

Uses of Percentiles

Many tests and instruments use percentile ranks for the gradation and reporting of scores to examinees. A

percentile rank score is neither a raw score, like in the examples above, nor a proportion or percent correct related to an examinee's performance on an instrument. Instead, the percentile rank is a measure of an individual's performance level relative to a reference (or comparison) group. The reference group is designated with consideration to the test's purpose. For example, when administering an educational standards test, the reference group could be the general location in which a school is located, an entire state, or an entire nation. The score that is reported is the p th percentile, indicating how well the examinee performed on the test relative to the rest of the reference group.

National and local standardized tests often include a percentile rank in addition to a raw score when reporting an individual's examination results. As illustrated below, one use of these scores is to see where an individual stands among his or her peers who also took the exam. Another use allows others, such as college admissions boards, to compare results from the current examination with students who took other versions of the test, or who took it in earlier or later years.

Another use of percentiles is for the classification of data. As previously stated, a person with a percentile rank of p splits the data into two groups, where $p\%$ of the reference group received the same or lower score while the remaining $(100 - p)\%$ of the group received higher scores. The percentile rank can also be used to mark a minimum level of proficiency, or a cut score. If a test is designed to single out the top $p\%$ of individuals possessing a level of a trait, those examinees who receive a percentile rank of $(100 - p)$ or greater should be investigated for inclusion.

A test that rank orders an examinee based on percentile ranks is said to be norm-referenced, because the examinee is only compared to others, and the examinee's raw score is not compared against some pre-set criterion. Percentile ranks are often used in norm-referenced settings, as when, for example, determining which students are at the head of their class, or deciding who the top-performing employees are when awarding bonuses or raises. Contrarily, if a school required the same minimum score on a test from year to year for admission, or if a company awarded bonuses only to salespeople who brokered a given number, this would be a criterion-referenced situation.

Test Equating

Percentile rankings are not only used when reporting results of standardized tests. In the field of test equating, one is interested in equating the set of scores for one instrument to those scores found on another instrument. There are many versions of equating found

in classical test theory (CTT), such as mean, linear, and equipercentile test equating. In CTT, the beauty of equipercentile equating is that it is a nonlinear method.

Consider the situation of having two different tests, Test A and Test B, that measure the same constructs but consist of different questions. Table 1 shows an example of what the two test forms A and B might look like. For both tests, the raw score is reported along with the proportion of examinees who received that score and the cumulative proportion of all scores at that point or lower. The cumulative proportion of examinees for each score is the same as the percentile ranking of that score. One can immediately see that the two tests are not equivalent: Test A contains 10 questions and Test B contains 15 questions. This fact alone will give the possibility of a higher raw score on Test B, simply due to the larger number of questions.

In order to be able to compare performance on Test A to performance on Test B, one can compare percentiles instead of raw scores. The most direct way of finding equivalent scores for these two test forms is to compare the raw scores from each test that have equivalent percentiles.

Example

Given the two tests, A and B, as outlined in Table 1, compare the 65th percentiles for the two forms. On Test A, a raw score of six questions correct is the 65th percentile; on Test B, a raw score of eight questions correct is the 65th percentile. Although the raw score on Test B is higher than that for Test A, the scores are considered to be equivalent because they are the same percentile; an examinee with a raw score of 6 on Test A and an examinee with a raw score of 8 on Test B have done equally well, relative to all other participants. Likewise, if an examinee were to correctly answer six questions on Test A, then he or she would likely answer approximately eight questions correctly if the examinee were to take Test B, and vice versa. The method of equating tests via matching percentiles is called equipercentile equating.

In order to illustrate the nonlinearity of the equipercentile equating method, one can pair raw scores by matching the percentile ranks from the tests being equated and then plot these matched pairs for a graphical representation, as in Figure 1. In the case of Test A and Test B in our example, one can pair raw scores from the 5th, 25th, 35th, 55th, 65th, 70th, 75th, and 99th

Table 1 Raw Scores for Test A and Test B

<i>Test A</i>			<i>Test B</i>		
<i>Raw Score</i>	<i>Prob(Raw Score)</i>	<i>Cumulative</i>	<i>Raw Score</i>	<i>Prob(Raw Score)</i>	<i>Cumulative</i>
0	0.05	0.05	0	0.05	0.05
1	0.20	0.25	1	0.05	0.10
2	0.10	0.35	2	0.05	0.15
3	0.15	0.50	3	0.05	0.20
4	0.05	0.55	4	0.05	0.25
5	0.05	0.60	5	0.10	0.35
6	0.05	0.65	6	0.10	0.45
7	0.05	0.70	7	0.10	0.55
8	0.05	0.75	8	0.10	0.65
9	0.05	0.80	9	0.05	0.70
10	0.20	1.00	10	0.05	0.75
			11	0.05	0.80
			12	0.05	0.85
			13	0.05	0.90
			14	0.05	0.95
			15	0.05	1.00

Figure 1 Test A and Test B Equipercetile Equating

percentiles, which are the only percentiles exactly matched on both tests. This graph can be used to estimate the expected score on an alternate test form when only one form had been administered, and one can interpolate equal raw scores on two exams. For example, if an examinee gets a raw score of 5 on Test A, we can see that that is the equivalent of a raw score of around 7.5 on Test B.

One major drawback to equipercetile equating, however, is that estimation for raw scores higher than or lower than those actually observed is not possible because all percentiles are accounted for in the data actually at hand. While one is often not interested in the properties of a test—like discrimination—for those obtaining low scores, it does pose problems for tests where high scores are of interest.

PIE CHART

A pie chart is a way of displaying data in which a circle is divided into segments (or “slices”) that reflect the relative magnitude or frequency of the categories. For example, the world’s population is divided among the continents as in Table 1. In a pie chart based on these data (Figure 1), the segment for Africa would constitute 13.72% of the total world population, that for Asia 60.63%, and so forth.

Pie charts are most often used to display categorical (i.e., nominal) data, and less often ranked or ordinal data. They are never used to show continuous data, for which line charts are the obvious choice. After a brief history of the pie chart, this entry describes variations of and problems with pie charts and then enumerates guidelines for making better pie charts.

A Brief History

The pie chart was probably first used by William Playfair, in a book published in 1801 called *The Statistical Breviary*. In it, he used circles of different sizes to represent the areas of the various countries in Europe and how they changed over time.

The circles were colored to indicate whether the country was a maritime nation (green) or not (red), and some were divided into slices to reflect the ethnic backgrounds of the residents. In a previous book, Playfair had used overline charts and line charts for the first time. However, possibly due to his reputation as a shady businessman, pie charts were not adopted in the United Kingdom for nearly 100 years, although they were better received in Europe.

Variations

In an *exploded pie chart*, one segment is separated from the rest. This can be done either to highlight that

Table 1 Population of the World’s Continents

Continent	Population (in 000,000s)	Percent of Total
Africa	878	13.72
Asia	3,879	60.63
Europe	727	11.36
North America	502	7.85
Oceania	32	0.50
South America	380	5.94
Total	6,398	100

Figure 1 Pie Chart Based on the Data in Table 1

segment as deserving of special attention, or because that slice is so small that it would otherwise be overlooked. In a *polar area diagram*, all of the segments have the same angle and differ from each other in terms of how far each slice extends from the center. Although this type of chart is often attributed to Florence Nightingale (and, indeed, is sometimes referred to as a Nightingale rose diagram), it was likely first used in 1843 by Léon Lalanne.

Problems With Pie Charts

Despite their ubiquity in newspapers, magazines, and business presentations, pie charts are rarely used in the sciences. They are pleasing to look at, but it is difficult to draw conclusions about the numbers that they represent. One major problem is the interpretation of the area of the individual segments. Viewers can easily discriminate among lines of different lengths, as in overline charts and histograms. They are less accurate, though, in discerning differences among areas and angles. Doubling the length of a line makes it look twice as long, but doubling an area makes it appear 70% larger. If the slices of a pie chart differ from each other only slightly, people have much more difficulty rank-ordering them than if the data were presented as overlines. Viewers also have difficulty interpreting angles; they tend to underestimate acute angles and overestimate obtuse ones. Furthermore, the same angles are seen as different if they are oriented differently (e.g., the slice extending vertically versus horizontally from the center).

Some chart users attempt to avoid this problem by placing the percentage or count either inside the slice or just outside it. However, this does violence to the

purpose of a graph, which is to allow the viewer to quickly see relationships among categories. If numbers are required in order for the viewer to do this, it would be better to use a table rather than a graph.

A second problem is that it is nearly impossible to compare the size of slices across two or more pie charts. Unless the slices both begin at the 12-o'clock position, comparing them imposes a heavy cognitive demand. The viewer is required to mentally rotate the slice in one pie until its left margin is at the same angle as that of the comparable slice in the other pie, while at the same time preserving the internal angle of the slice, and then judging whether the right margins are at the same angle. This is not just difficult—it is nearly impossible to do accurately.

Rules for Making Better Pie Charts

If a pie chart is used, there are a number of guidelines for making them easier to interpret.

1. The number of categories should be relatively small. If there are only two categories (e.g., male/female, responders/nonresponders), a chart of any type is superfluous, and the information would be better presented within the text. When there are more than four to six categories, the segments become too small to easily differentiate.
2. Values that differ considerably from one another are easier to differentiate than values that are nearly identical. If some segments have similar areas, a different type of graph should be considered.
3. The names of the segments should be placed near the segments themselves, not in a legend box alongside or beneath the chart. It is cognitively much more demanding for the viewer to look at a segment, remember its color or shading, and then search for that attribute in a list of the categories. However, many widely available computer programs that draw graphs cannot do this easily and place the legend in a separate box.
4. Unless the data are ordinal, the segments should be arranged so that they are in descending order of magnitude. The first should start at the 12-o'clock position, and the slices should be arranged in a clockwise direction.
5. Three-dimensional (perspective) pie charts should never be used. Although they are often found in nonscientific publications and presentations, they are extremely misleading. Tilting the angle distorts the perceived relationships among the segments, and the greater the degree of perspective, the greater the distortion. Especially when the segments are in different colors

and one or more slices are exploded, the viewer often focuses more on the design than on the content.

PILOT STUDY

In research, a pilot study refers to either a trial run of the major research study or a pretest of a particular research instrument or procedure. Ideally, such studies should be conducted using participants who closely resemble the targeted study population. Pilot studies are particularly valuable in situations where little is known about the research topic, or when executing unprecedented research instruments. The major objective of a pilot study is to discover problems prior to the main study so that the researcher can take corrective action to improve the research process, and thus the likelihood of success of the main study. This entry discusses the importance of pilot studies, the procedures and evaluation of pilot studies, and problems associated with them.

Importance

All researchers seek to obtain reliable and valid data to answer their research questions or hypotheses. However, although researchers generally try to be quite meticulous, measurement error can still easily occur as a result of problems with questionnaire design, improperly trained interviewers, and so on. Therefore, pilot studies should be a normal component of good research design. Such studies can save researchers both time and money because logistical problems and other design deficiencies can be identified prior to the real study, and corrections and adjustments can be made before the main study is executed.

In some cases, more than one pilot study may be necessary. For example, the first pilot study may be an

expert review or focus group to help determine and/or refine the types of questions that should be included in a particular questionnaire. The research instrument can then be prepared and a second pilot study conducted to evaluate other issues, such as clarity of instructions, clarity of questions, and so on. Alternatively, if the initial pilot study had started with an evaluation of the questionnaire, this may have revealed such an abundance of problems that it may be necessary to conduct a second pilot to ensure that all or most of the identified problems are properly addressed to minimize or avoid measurement error.

Pilot studies have been in use since the 1940s. They are suitable for both quantitative and qualitative studies and are helpful for determining suitability of instruments, data collection procedures, and sample population, to name a few. Additionally, pilot studies also serve other useful purposes. For example, pilot tests may help to convince funders that the particular study is worthy of funding. Or, in the case of a trial run, the pilot may reveal that the proposed relationship between variables may not exist, thus signaling to the researcher that the main study is no longer warranted. Pilot studies may even signal problems with local politics.

Procedure

The sample population for a pilot study should closely mirror the intended targeted population. Thus, if the targeted population is university graduates, then the pilot participants should also be university graduates. Generally, a convenience sample is used with about 50 to 100 participants—some studies may use even fewer participants. Compared to a pretest, a trial run or feasibility study is much more comprehensive because it is, in effect, a miniature version of the real research study. This means that it is executed using the same administration procedures that would be used to carry out the real study. Thus, if the research study intended to use interviews as the primary data collection method, the trial run should not use only experienced interviewers for the pilot because these interviewers would already be trained to deal with problematic situations.

If interviews are the primary data collection methodology, a pilot may focus on logistical issues such as interviewers' ability to follow survey directions, interviewers' ability to record data, time required to record responses, and so on. Thus, if the pilot study revealed that the average interview time exceeded the budgeted time, alternative strategies such as reducing the number of questions, using a smaller sample, or better training of interviewers may need to be considered to

remedy this problem. The pros and cons of each strategy would need to be carefully considered because each strategy would have different implications for the research.

Likewise, if a self-administered questionnaire is being used, a pilot may focus on issues such as clarity of instructions for completing the survey, clarity of questions, and simplicity of questions, to name a few. Thus, if the pilot study revealed that Question 1 was ambiguous, Question 1 would need to be reworded. If most respondents circled—rather than shaded—their answers on the Likert scale, this would clearly indicate that the instructions were not clear. The instructions would need to be reworded; the researcher may decide to clarify the instructions by including an example of how responses should be shaded (e.g., 1 2 3 4).

Evaluation

Once the pilot study is completed, the next step is to evaluate the results. Interviewer debriefing is the most common form of evaluation. This process involves the researcher meeting with all of the interviewers in a group and discussing encountered problems. Often, standardized forms are used to record problems/deficiencies revealed from the pilot study. These forms may be completed by the interviewer, or, in the case of a pilot of a self-administered survey, the participant may be asked to fill out the form to provide general feedback on the instrument. Encountered problems are discussed in detail, and solutions are then identified to address any deficiencies. The research methodology is then refined.

Problems With Pilot Studies

Pilot studies are undoubtedly helpful in identifying problematic issues in advance so that proactive action can be taken. Notwithstanding, a successful pilot study cannot guarantee success of the main study. During the actual study, other problems may be encountered that may not have been revealed by the pilot. For example, response rates may be much lower than anticipated, or contamination problems may surface if pilot participants are subsequently included in the main study. A more serious concern, however, may be if the research funding is terminated as a result of the pilot indicating that the study may no longer be original or warranted.

PLACEBO

When conducting a double-blind clinical trial to evaluate a new treatment, the investigator is faced with the problem of what to give the control group. If there is no existing acceptable and beneficial treatment against which the new treatment can be compared, the reasonable approach would be to give the control group no treatment at all, but this raises concerns that subjects may have hidden expectations or preferences that could influence the outcome. One solution is the use of a harmless “sham” treatment that is similar in all aspects such that the subjects and those administering the treatments cannot determine whether a subject is in the study group or the control group. This sham treatment is called the placebo. This entry discusses historical usage, difficulties with the placebo research design, and the placebo effect.

Historical Usage

The term *Placebo Domino* . . . (“I shall please the Lord . . .”) appears in a 5th-century translation of the Bible. By the end of the 18th century, *placebo* was used as a medical/pharmaceutical term, denoting a remedy designed to please the patient rather than effect any specific treatment. This sense of a deceptive yet morally acceptable therapy remained until the mid-20th century, when the true function of placebos came under critical scrutiny. Since 1955, the literature has generally advised caution in the use of the placebo, and has encouraged awareness of the limits of the effects of placebos, but their use has remained advisable when conducting randomized clinical trials.

Difficulties With Placebo Design

Under ideal circumstances, both the active pharmaceutical treatment being evaluated and the placebo being used for the control group will be contained within similar gelatin capsules, tablets, or solutions, rendering

them indistinguishable from each other as far as the participants are concerned. But when the active treatment under investigation has a distinct appearance or other characteristic such as strong taste, odor, or texture, or is a physical intervention, manipulation, or some invasive procedure, designing the placebo can present a challenge. How can the treatment and placebo be made indistinguishable from each other? And what if there are ethical issues for either group? Examples of each of these challenges are presented in this section.

Maintaining Similarity

Most traditional Chinese medicine (TCM) remedies are often aromatic, dark-colored, bitter, and pungent. In a randomized crossover clinical trial of a TCM preparation for atopic eczema, all of these characteristics had to be simulated in the preparation of the placebo but without any therapeutic effect remaining. Participants who dropped out because of unpalatability were found to be just as likely in the placebo phase of the crossover trial as when the active treatment was being taken, suggesting that the organoleptic characteristics of the placebo were successfully indistinguishable from that of the active treatment.

Ethics

In a study of the effectiveness of fetal brain cell implants for intractable Parkinson's disease, an ethical debate emerged over the use of nonimplant surgical control groups. Clearly, a theoretically perfect control group would have the presurgical preparation, opening of the skull, insertion of probes, and the closure procedure, but without the implant of fetal brain cells. Ethical objections were raised about the surgical risks for the control group, who would be without any potential benefit. But the need for the sham surgery was reinforced when it was learned that subjects receiving the sham procedure typically exhibited improvements in their Parkinson's symptoms for up to 6 months and were indistinguishable from patients who received the same surgery but with active (implant) treatment. The investigators were unable to attribute the observed improvements to either observer bias or the natural history of the disease.

Placebo Effect

The placebo may produce a clinical effect by itself, arising perhaps from the participants' beliefs that the treatment should be effective, or from their subconscious preference to reveal a beneficial outcome from the

treatment. This is known as the *placebo effect* and must be carefully considered when evaluating any effects that may be attributed to the treatment being investigated. The previous example is a curious case of a placebo effect in which a substantial improvement was documented in the group that underwent surgery without implantation. It raises questions about exactly which component of the true surgical intervention constituted the effective treatment—was it really the implanted cells, or the neural stimulation of the surgical intervention, or some other component? Without the invasive and controversial placebo arm of the study, this question might never have been raised.

Determining the nature and scope of the placebo effect has long been subject to considerable controversy. Recent experimental results support two theories about placebo responses: *conditioning*, which proposes that changes in the body occur as a result of a stimulus that has been previously associated with active, positive processes; and *expectancy*, which proposes that changes occur in the body because the individual expects them to.

An Example of the Placebo Effect

Irritable bowel syndrome is a common condition typically associated with consistent pain and bloating in the absence of any other obvious diagnosis. In a revealing study, a team led by Ted Kaptchuk did not provide any real treatment at all, but randomly divided 262 adults with IBS into three groups. The first group was told only that it was being studied and that outcomes were being collected. The second group received sham acupuncture (putting needles into the skin in a random way that is not based on the principles of acupuncture). The third group received sham acupuncture and an "enriched relationship" with the doctor. Moderate or substantial improvement in their IBS was reported by 3% of those patients in the observation-only group, 20% among the procedure-only group, and 37% in the group with procedure augmented by enriched communication from their physician. In the absence of any specific treatment, all of these results must be classified as placebo effects.

The evidence remains equivocal, however. In 2001, a meta-analysis of clinical trials with treatment, placebo, and no-treatment arms concluded that placebos have small or no effects. But a re-analysis in 2005 revealed that in many cases, the placebo effect was robust and delivers results close to the treatment effect.

PLACEBO EFFECT

The placebo effect is any reaction to the administration of a placebo that is both clinically significant and salutary. A placebo is any treatment prescribed for a condition for which it is physically ineffective. The placebo effect has been successfully and repeatedly demonstrated on variables that are subjectively experienced, such as pain reduction, coping mechanisms, emotional well-being, and cognitions. The majority of research has centered on pain relief, also known as placebo analgesia. The magnitude of the effect and the percentage of those affected depend on a number of factors, but research indicates that approximately one third of individuals who receive a placebo believing it to be a potent treatment report a significant analgesic effect.

The research involving objective measures of beneficence has been more controversial. Although some studies have described a modest effect of placebos on objective measures of healing, recent meta-analyses have indicated that these effects are, overall, nonsignificant. Objective measures of well-being and healing may be indirectly affected by positive changes in expectations for successful treatment or symptom relief. Although these are purely psychological variables, they may have very real consequences, because chronic pain,

hopelessness, and a failure of usual coping strategies often occur during severe illness and are associated with a poor prognosis. In this entry, the history and elements of the placebo effect are described and implications and ethical considerations for research are discussed.

History of the Placebo Effect

The term *placebo* is a literal translation of the Latin phrase *I will please*. Its first documentation in an English dictionary did not occur until 1785. In 1920, T. C. Graves was the first to formalize the current conception of the medicine-like effects of placebo administration. In the 1950s, Henry Beecher attempted to quantify it. After a series of studies, he noted that the condition for which a patient was being treated greatly affected the percentage of those for whom a placebo alone was a satisfactory remedy. The effect, however, was much more prevalent than he expected, significantly influencing the amount of perceived pain in 30% of all patients.

A better understanding of the placebo effect spawned methodological transformations in the mid-20th century. Although placebo-controlled studies occurred on occasion throughout history, it was not until the 1930s that the widespread use of a dummy simulator was used as a means to test an experimental drug. This allowed researchers to compare the differences (or lack thereof) between the placebo effect of a specific medium on a specific condition and the drug effect on the same sample. Thus, experimenters could examine which drugs were significantly more effective than placebo treatment alone.

The inclusion of a placebo group is now standard practice in medical research. Drug manufacturers, prescribing physicians, and consumers demand assurance that medications or treatments are more effective than a placebo procedure. Therefore, before a treatment protocol or regimen is widely adopted, the placebo effect must be used as a baseline for such comparisons. Because the addition of a placebo group greatly complicates the research methodology and interpretation, the placebo effect is generally considered a necessary but burdensome aspect of medical research.

Elements of the Placebo Effect

There are three components that affect the magnitude and prevalence of a placebo effect: patient characteristics, researcher manipulation, and the characteristics of the placebo treatment itself.

Patient Characteristics: Expectation and Desire

The placebo effect is a psychosocial phenomenon, the result of social and individual expectations of the

intended effect of a treatment. The expectation of benefit by the client is considered the most important and influential factor involved in the placebo effect. Knowledge that any treatment is a placebo will, generally, nullify any placebo effect. This seems an obvious but salient point: Without hopeful expectations, a client will not garner the benefits of the placebo. In fact, it appears that when patients are administered real analgesics without their knowledge, they benefit significantly less than those who are openly administered the drug.

The central building block of patient expectancy occurs through classical conditioning. Medicinal placebos may be especially effective, because most people have had a history of being medicated effectively. An unconditioned stimulus (an active intervention) has been paired repeatedly with an unconditioned response (benefit). The active intervention is then mimicked by the placebo intervention, resulting in the conditioned response of benefit. Conditioning has produced lasting placebo effects under falsified laboratory settings and through naturalistic field observation.

Specific levels of pretreatment expectations of post-treatment pain account for between 25% and 49% of the variance associated with that experienced after a placebo analgesic administration. Furthermore, patients have a tendency to overestimate the amount of pretreatment pain and underestimate the amount of post-treatment symptom reduction. The degree to which these memory distortions occur is highly correlated to pretreatment expectations of success.

Desire for an effective treatment can also create or enhance placebo effects. Although every patient seeks treatment because he or she desires to be free of symptoms, such avoidance goals are often not powerful enough to marshal a noticeable placebo effect.

Increasing the desirability of a placebo response can greatly enhance the effect. For instance, participants who believe particular responses to a medication are indicative of positive personality characteristics are more likely to report those responses than those who were not similarly motivated. Additional studies have determined that very subtle, nonconscious goals can influence the magnitude of the placebo effect. The results indicated that one will likely be influenced by a placebo if it suits his or her goals, even if those goals are not overtly conscious.

Finally, patients in great pain have an increased desire for any treatment to be effective. The greater the pain, the more likely a placebo response will occur.

Researcher Manipulation: Suggestion and Credibility

The researcher can drastically influence patient expectations of treatment through making suggestions and

enhancing credibility. Whereas suggestions usually occur on an overt, explicit basis, credibility is often a given of the therapeutic experience, both implicit and understood.

In Western society, there are certain symbols of healing credibility. Having one's own practice, wearing a white lab coat, displaying diplomas on the wall, and having a PhD behind one's name are all ways to establish expectancy through the appearance of expertise. When these culturally relevant tokens are assumed, the researcher becomes sanctioned as a healer, and the resultant credibility mobilizes the patient's expectancy and results in greater therapeutic gain.

The researcher can also enhance his or her trustworthiness and attractiveness to maximize credibility. An attractive, socially sanctioned healer is likely to inspire motivation and hope within the patient and is therefore more likely to elicit a placebo response.

A number of studies have examined the effect of overt verbal suggestions made by physicians and the client's resulting placebo effect. Direct allusions to the potency of a treatment are effective means of creating expectancies in patients and are easily manipulated by the researcher. Research indicates that the emphasis, tone, and content of even a small comment can greatly affect the magnitude of a client's placebo response.

Placebo Characteristics: Cultural Association With Potency

The characteristics of the placebo treatment itself can influence its effects. More accurately, the cultural significance of the method of placebo delivery can enhance its effectiveness. Apparent invasiveness and strength of the intervention are ordinally related to the strength of the placebo effect for that mode of intervention. For instance, most Americans expect a larger benefit from surgery than from only a single injection from a hypodermic needle. Most Americans also expect more benefit from that same injection than from a simple pill. An analysis of the amount of placebo-induced benefit from each form shows the same trend: The placebo effects for one sham surgery are greater than those for a single injection, which are greater than those from a single pill, even if they all promise the same results.

Implications for Research

The placebo effect occurs during every medical or psychological intervention into which a participant carries an expectation or motivation for success. To some extent, it affects every participant. It is not possible to determine how the elements of the placebo effect will

interact, and it is therefore impossible to predict to what extent an individual will exhibit a placebo response. Given this unpredictability, the placebo effect must be taken into account and quantified to accurately assess the efficacy rates of a treatment.

To test the efficacy of a particular drug on a particular condition, participants are often randomly assigned into one of three conditions: the experimental group (E), the placebo group (P), and the natural history group (NH). The experimental group receives the active drug. The placebo group receives an inert substance through a procedure identical to that used to administer the experimental drug. In double-blind procedures, neither the researchers nor the participants know which participants belong to the placebo-control group and which belong to the experimental-active group. This practice eliminates any conscious or unconscious experimenter bias that creates expectations that may differentially inflate the placebo effect. Finally, the natural history group does not receive any intervention at all. Participants in this group are often wait-listed and monitored until the experimental trial is complete.

By creating formulas that assess the differences between the three groups, researchers can quantify the magnitude of the placebo effect, the efficacy of the active drug, and the overall effect of the treatment. The outcome of the natural history group provides an absolute baseline (NH). This represents, on average, the course of the condition when untreated. Individuals in this group are susceptible to using methods that differ from the standard treatment of the other two groups, such as homeopathy, vitamins, or exercise. Such extraneous variables should be considered and carefully controlled.

The strength of the placebo effect (PE) is determined by examining the differences between the natural history group and the placebo group ($PE = P - NH$). This formula indicates the extent to which the elements of a placebo have influenced the subjective responses of some participants.

The efficacy of the experimental treatment can be determined two different ways. The absolute efficacy (AE) is determined by the difference between the experimental group and the natural history group ($AE = E - NH$). This formula represents the total effect of the treatment. Although it is important that any treatment be superior to no treatment at all, this is usually not the figure of interest. Any inert substance, if properly administered, can achieve some level of success (the placebo effect). The active component (AC) efficacy is the difference between the experimental group and the placebo group ($AC = E - P$). This formula accounts for the placebo effect and is therefore the standard by which the efficacy of any treatment is judged.

Because placebo-controlled studies involve the administration of a physically inactive substance, treatment modes that do not require physical interaction, such as psychotherapy, have not previously been viewed as amenable to placebo research. There is a great deal of controversy surrounding what can be considered a placebo in noninvasive treatments, and how that definition can be used in outcome research.

Ethical Considerations of Placebo Research

There are a number of ethical considerations when using placebos in research. First, the use of placebos is considered deception. Research ethicists and legal experts generally advocate a conservative use of placebos in research to protect researchers and clinicians from unwarranted ethical violations and litigation. They condone their use only under certain conditions: There is no efficacious alternative therapy, the research will result in practical benefit, the duration of the trial will be short, there is little risk that the participant's condition will worsen, the participant has been fully apprised as to the state of the biomedical knowledge, and the participant has signed a fully informed consent that complies with the applicable legal and ethical codes. Furthermore, once the study has begun, it may become unethical to continue the clinical trial once an experimental treatment has shown definitive evidence of efficacy. If this occurs, researchers are obligated to inform participants in the placebo group (and any other comparison groups) and offer them the experimental treatment.

In general, placebo-controlled randomized trials are complicated, require vast resources, and are ethically and legally perilous. They can provide valuable information but are appropriate only under specific conditions and should not be attempted haphazardly.

POISSON DISTRIBUTION

The Poisson distribution is a discrete probability distribution that is often used for a model distribution of count data, such as the number of traffic accidents and the number of phone calls received within a given time period. This entry begins with a definition and description of the properties of the Poisson distribution, which is followed by a discussion of how the Poisson distribution is obtained or estimated. Finally, this entry presents a discussion of applications for the distribution and its history.

Definition and Properties

The Poisson distribution is specified by a single parameter μ , which determines the average number of occurrences of an event and takes any positive real number (i.e., $\mu > 0$). When a random variable X , which can take all nonnegative integers (i.e., $X = 0, 1, 2, \dots$), follows the Poisson distribution with parameter μ , it is denoted by $X \sim \text{Po}(\mu)$. The probability mass function of $\text{Po}(\mu)$ is given by

$$P(X = x) = \frac{\mu^x e^{-\mu}}{x!}, \quad x = 0, 1, 2, \dots,$$

where e is the base of the natural logarithm ($e = 2.71828\dots$). The mean of X is μ , and the variance is also μ . The parameter μ is sometimes decomposed as $\mu = \lambda t$, where t is the length of a given time interval and λ denotes the “rate” of occurrences per unit time.

Figure 1 depicts the probability mass functions of the Poisson distributions with $\mu = 1, 5$, and 10, respectively. The horizontal axis represents values of X , and the vertical axis represents the corresponding probabilities. When μ is small, the distribution is skewed to the right. As μ increases, however, the shape of distribution becomes more symmetric and its tails become wider.

Figure 1 Probability Mass Functions of the Poisson Distributions With $\mu = 1, 5$, and 10

The Poisson distribution arises as a result of the stochastic process called the *Poisson process*, which builds upon a set of postulates called the *Poisson postulates*. Roughly speaking, the Poisson postulates posit the following conditions on the probability of events occurring in given time intervals: (a) The numbers of events occurring in nonoverlapping time intervals are independent, (b) the probability of exactly one event in a very short (i.e., infinitesimally short) time interval is approximately proportional to the length of the interval, (c) the probability of more than one event in a very short interval is much smaller than the probability of exactly one event, and (d) the above probability structure is unchanged for any time interval. These postulates lead to a set of differential equations, and solving these equations for the probability of the number of events occurring in a given time interval produces the Poisson distribution.

The way by which the Poisson distribution is derived provides a basis for the distribution to be used for a model of rare events; the Poisson postulates state that the event occurs rarely within each small time interval but is given so many opportunities to occur. In this sense, the Poisson distribution is sometimes called *the law of small numbers*.

Relationship to Other Probability Distributions

The Poisson distribution is obtained as a limiting distribution of the *binomial distribution* with probability p and the number of trials n . Let $\mu = np$, and increase n to infinity while μ is held constant (i.e., p approaches 0). The resulting distribution is $\text{Po}(\mu)$. This fact, in turn, implies that the Poisson distribution can be used to approximate the binomial distribution when n is large and p is small. This is of great use for calculating binomial probabilities when n is large, because the

factorials involved in the binomial probability formula become prohibitively large.

If the number of occurrences of an event in a given period of time t follows $Po(\lambda t)$, then time T between two successive occurrences (which is called the waiting time) is also a random variable and follows the *exponential distribution* with mean $1/\lambda$. Thus, if occurrences of an event in a given time interval t follow the Poisson distribution with rate λ , then the waiting time follows the exponential distribution and the average waiting time for the next event to occur after observing an event is $1/\lambda$.

When μ is large, $Po(\mu)$ is well approximated by the normal distribution $N(\mu, \mu)$ because of the central limit theorem. Thus, if $X \sim Po(\mu)$, then $Z = (X - \mu) / \sqrt{\mu}$ approximately follows the standard normal distribution $N(0,1)$, from which probabilities regarding X are obtained easily. For the probability calculation, the chi-square distribution can also be used; the probability that $X \sim Po(\mu)$ takes a value less than or equal to x is given by $P(X \leq x) = P(\chi^2_{2(x+1)} > 2\mu)$, where the right-hand side denotes the probability that the chi-square random variable with $2(x+1)$ degrees of freedom takes a value greater than 2μ .

Estimation

The parameter μ can be estimated by the sample mean of a random sample $X_1, X_2, \dots, X_n$ from $Po(\mu)$. That is, $\hat{\mu} = \bar{X} = \sum_{i=1}^n X_i / n$. It is an unbiased estimator with the minimum variance, which is μ/n , as well as the maximum likelihood estimator.

For the interval estimation, approximate $100(1 - \alpha)\%$ confidence limits (μ_L, μ_U) for μ can be found by

$$\mu_L = 0.5\chi^2_{2x, \alpha/2}, \mu_U = 0.5\chi^2_{2(x+1), 1-\alpha/2},$$

where x is an observed value of $X \sim Po(\mu)$, and $\chi^2_{df, p}$ is the value of the chi-square variable with degrees of freedom df , which gives the lower-tail probability p . If μ is expected to be large, then the normal approximation may be used as well.

Applications

Poisson Regression/Loglinear Models

Poisson regression is a regression model used for count data. Especially when used for contingency tables, it is called the *loglinear model*. Poisson regression models are formulated as *generalized linear models* in which the canonical link function is the log link and the Poisson distribution is assumed for the dependent variable.

In the standard case in which there are K linear predictors $x_1, x_2, \dots, x_K$ and the dependent variable Y ,

which represents a count given x s, the Poisson regression model is expressed by the equation

$$\ln[\mu(x)] = b_0 + b_1x_1 + \dots + b_Kx_K,$$

where $\ln$ is the natural logarithm, $\mu(x)$ is the expected count of Y given $x_1, x_2, \dots, x_K$ and $b_0, b_1, \dots, b_K$ are the regression coefficients. The distribution of count Y given $x_1, x_2, \dots, x_K$ is assumed to be $Po[\mu(x)]$, where the log of the expected value $\mu(x)$ is determined by a linear combination of predictors $x_1, x_2, \dots, x_K$. The regression coefficients are estimated from N sets of observed data $(Y_i, x_{i1}, x_{i2}, \dots, x_{iK}), i = 1, 2, \dots, N$.

When applied to a contingency table, the above linear Poisson regression model is equivalent to the loglinear model, that is, a model for expected cell frequencies. Suppose that the table comprises two factors, A (row factor) and B (column factor), whose levels are denoted by $i = 1, \dots, r$ and $j = 1, \dots, c$, respectively. Let Y_{ij} be the frequency of the (i, j) cell of the table and μ_{ij} be the corresponding expected cell frequency. The Poisson loglinear model assumes that $Y_{ij} \sim Po(\mu_{ij})$, and

$$\ln(\mu_{ij}) = \lambda + \lambda_i^A + \lambda_j^B + \lambda_{ij}^{AB},$$

where λ is the grand mean, λ_i^A and λ_j^B are the main effects of the i th row and the j th column, respectively, and λ_{ij}^{AB} is the interaction for the (i, j) cell, as in the usual two-way ANOVA model. The above model is called the saturated model, by which the observed cell frequencies are completely reproduced by the estimates of μ_{ij} . Then, various hypotheses can be tested by setting certain effects to zero. For example, setting all interactions to zero (i.e., $\lambda_{ij}^{AB} = 0$ for all i and j) leads to the model of independence, that is, there is no association between Factors A and B , and each cell frequency can be estimated from its marginal frequencies. Further, setting all the A main effects to zero (i.e., $\lambda_i^A = 0$ for all i) implies that the cell frequencies do not differ by different levels of A . A model is tested by comparing its goodness of fit with a more general model. For example, the independence model can be tested against the saturated model. If the goodness of fit of the independence model is not significantly worse than that of the saturated model, the independence model is accepted.

Poisson Process Model for the Number of Misreadings

Frederick Lord and Melvin Novick introduced several measurement models, which were originally proposed by Georg Rasch, that were based on Poisson distributions. One of the models was intended for the number of misreadings of words in an oral reading test, which Rasch considered measures one aspect of reading ability. As in other measurement models that Rasch proposed, such as

the one-parameter logistic item response model (i.e., the Rasch model), his intention was to estimate individual ability separate from the difficulty of texts. This is the key feature of his Poisson process model as well.

Suppose that there are several texts, each of which is denoted by g and consists of N_g words. Rasch assumed that the probability that person i misreads a given word in text g is a ratio of the text's difficulty, δ_g , to the person's ability, ξ_i , that is, $\theta_{gi} = \delta_g / \xi_i$, where θ_{gi} is the probability of misreading of a given word in text g by person i . The text difficulty parameter δ_g takes a value between 0 and 1, with the most difficult text having $\delta_g = 1$. The person ability parameter takes a value from 1 to infinity, with the least able person having $\xi_i = 1$ (this is a hypothetical person who certainly misreads any word). These constraints are required to uniquely determine values of the parameters. Then, with a sufficiently long text, a small probability of misreading, and independence of individual misreadings given the person's ability, the number of misreadings in text g by person i follows the Poisson distribution with parameter $\lambda_{gi} = N_g \theta_{gi} = N_g \delta_g / \xi_i$, which represents the expected number of misreadings in text g by person i .

After observing a data matrix, which consists of x_{ig} , the number of misreadings by person i ($= 1, \dots, N$) and text g ($= 1, \dots, G$), we can estimate relative sizes of the text difficulty parameters δ_g and person ability parameters ξ_i separately as if they were the main effects in two-way ANOVA. Then, the estimates are rescaled so that they satisfy their constraints.

History

Siméon-Denis Poisson, a French mathematician and physicist, discovered the Poisson distribution in the 19th century (although Abraham de Moivre provided the same result even earlier in the 18th century). In his work in probability theory, Poisson is also known for his introduction of the term *the law of large numbers* (*la loi des grands nombres* in French), which was originally called *Bernoulli's theorem* after its original discoverer, Jakob Bernoulli. Poisson found the distribution by considering the limit of the binomial distribution as described above. He applied it to modeling the deliberations of juries, but it did not receive popularity at that time. Later, the Poisson distribution drew the attention of several mathematicians, such as Ladislaus Bortkiewicz, who gave the name the law of small numbers to the distribution; Thorvald Thiele; and William Gosset. Now the Poisson distribution is even considered as a standard distribution for a discrete random variable, as the normal distribution is the standard distribution for a continuous random variable.

POLYCHORIC CORRELATION COEFFICIENT

The polychoric correlation coefficient, ρ , is used for correlation when the data consist of observations from two ordinal variables, each having an arbitrary number of response categories. Strictly speaking, the polychoric correlation coefficient estimates the correlation between two unobserved bivariate normal variables assumed to underlie the observed ordinal variables. The polychoric correlation coefficient is a generalization of the tetrachoric correlation coefficient, a statistic used to estimate correlation based on two dichotomous variables. Under assumptions, the polychoric correlation provides a correlation estimate that is entirely free of the attenuation caused when two normally distributed variables are “crudely categorized”—that is, when they are reduced to sets of ordinal categories. This attenuation in the correlation estimate leads to bias in parameter estimates when the biased correlations are used in methods such as factor analysis or structural equation modeling. By contrast, parameter estimates from analysis of polychoric correlations tend to be unbiased. Although the polychoric correlation coefficient is built upon an assumption of underlying bivariate normality, simulation studies show that the polychoric correlation coefficient is somewhat robust to violations of this assumption. The polychoric correlation coefficient will tend to yield a stronger (in absolute value) correlation estimate than a Pearson product-moment correlation applied to ordinal

variables, especially when the number of response categories for each variable is small (less than five) and when the distributions of the ordinal variables are skewed. Yet the polychoric correlation coefficient, which traces its origins to Karl Pearson's work in the early 1900s, shares the same expected value as the Pearson product-moment correlation. By contrast, nonparametric correlation coefficients such as Spearman's rank-order correlation and Kendall's τ_b have different expected values, making them less attractive as substitutes for the Pearson product-moment correlation. The polychoric correlation coefficient has been used prominently for factor analysis and structural equation modeling of ordinal data. The statistic has definite advantages over some alternative approaches but also has substantial drawbacks. However, continuing innovation in structural equation modeling, as well as problems with the use of the polychoric correlation for this purpose, seem likely to make this application of the polychoric correlation coefficient less prominent in the future.

Estimating the Polychoric Correlation Coefficient

Imagine two variables X and Y , which might represent responses to two items on a questionnaire, where those responses were limited to a set of ordered and mutually exclusive categories. The items might be two Likert scale items, each with a set of response categories labeled *strongly disagree*, *disagree*, *neither agree nor disagree*, *agree*, and *strongly agree*. Researchers will often assign numbers to these categories, such as 1, 2, 3, 4, and 5. A researcher who then uses these numbers to compute statistics—such as a Pearson product-moment correlation between X and Y —is implicitly assuming that the variables X and Y have at least interval scale. If the variable has only ordinal scale, however, then the specific numbers assigned to different categories signify only the ordering of the response categories—they cannot be used for computation. Unlike the Pearson product-moment correlation, the polychoric correlation is derived, not computed from the response category scores.

The logic of the polychoric correlation coefficient assumes that the observed ordinal variable X is a categorization of an underlying continuous, normally distributed variable, X^* . The g response categories of X result when the normal distribution of X^* is divided by $g - 1$ unknown thresholds τ_i :

$$\begin{aligned} X &= \alpha_1 \text{ if } -\infty \leq X^* < \tau_1 \\ X &= \alpha_2 \text{ if } \tau_1 < X^* < \tau_2 \\ &\dots \\ X &= \alpha_g \text{ if } \tau_{g-1} < X^* \leq \infty. \end{aligned}$$

Similarly, the h categories of Y result from categorization of a normally distributed Y^* :

$$\begin{aligned} Y &= \beta_1 \text{ if } -\infty \leq Y^* < \tau_1 \\ Y &= \beta_2 \text{ if } \tau_1 < Y^* < \tau_2 \\ &\dots \\ Y &= \beta_h \text{ if } \tau_{h-1} < Y^* \leq \infty. \end{aligned}$$

Estimating the polychoric correlation, then, involves estimation of $(g - 1) + (h - 1) + 1 = g + h - 1$ parameters (the thresholds plus the correlation) from the $g \times h$ cross-tabulation of X and Y . The log likelihood for a simple random sample of size n from an infinite population is

$$\ln L = \ln C + \sum_i^g \sum_j^h n_{ij} \ln \pi_{ij},$$

where C is a constant, n_{ij} is the number of observations in cell i, j , and π_{ij} is the probability of a single observation falling into cell i, j . Given the underlying assumption of bivariate normality, then

$$\begin{aligned} \pi_{ij} &= \Phi_2(i, j) - \Phi_2(i - 1, j) - \Phi_2(i, j - 1) \\ &\quad - \Phi_2(i - 1, j - 1), \end{aligned}$$

where Φ_2 is the bivariate normal distribution function with correlation ρ .

Alternative Approaches to Estimation

In practice, researchers have developed at least three major approaches to estimation. In the early 20th century, in the pre-computer era, scholars commonly estimated the thresholds from the marginal counts of the cross-tabulation table. With the scale of the ordinal variables being arbitrary, threshold values were chosen from the standard normal Z distribution, based on the proportion of responses in each category. For example, if 2.5% of responses to X were in the lowest response category, the researcher would set a threshold value of -1.96 between the lowest category and the next lowest. If 47.5% of responses fell into the next response category, then the next threshold value would be 0.00 . With the threshold values fixed, the researchers would then estimate the polychoric correlation by setting the derivative of the likelihood function with respect to the correlation equal to zero:

$$\frac{d \ln L}{d \rho} = 0,$$

then solving for the correlation. An alternative approach, made more feasible with computer assistance, is to

estimate all $g + h - 1$ parameters simultaneously via maximum likelihood. Differences between these two approaches tend to be small, which recommends the older, faster, two-stage method. Either way, estimates of the polychoric correlation tend to be unbiased when the observed distribution is symmetric or with moderate levels of skew.

Both of these methods estimate each polychoric correlation one at a time. Researchers with a number of observed variables may actually want a matrix of polychoric correlations. When the correlations are estimated in this pairwise fashion, however, there may be inconsistencies across the matrix, leading to a correlation matrix that is not well-conditioned for multivariate analysis. This is particularly a problem for researchers who want to apply factor analysis or structural equation modeling (SEM) to the matrix of polychoric correlations. However, simultaneous estimation of an entire matrix of polychoric correlations, assuming an underlying multivariate normal distribution, leads to complex integrals. Researchers have attempted to make this problem more tractable through reparameterization, but this multivariate approach may still be computationally infeasible for moderately sized models, even with modern computing power. As a result, most current software uses a bivariate approach when estimating polychoric correlations.

Polychoric Correlations in Structural Equation Modeling

However, using polychoric correlations in structural equation modeling of ordinal variables raises further problems. Maximum likelihood estimation of a structural equation model assumes that the elements of the covariance matrix being analyzed follow a joint Wishart distribution. This assumption involves only limited negative consequences when researchers analyze matrices of Pearson product-moment correlations. However, the elements of a matrix of polychoric correlations do not follow a joint Wishart distribution. Although parameter estimates from SEM analysis of polychoric correlations are essentially unbiased under assumptions, the χ^2 fit statistic will be substantially inflated and standard errors will be unreliable.

Researchers have attempted to address this problem by applying an asymptotically distribution-free (ADF) approach to SEM analysis of polychoric correlations. The ADF approach uses a discrepancy function of the form

$$F = (\underline{s} - \underline{\hat{\sigma}})W^{-1}(\underline{s} - \underline{\hat{\sigma}}),$$

where $\underline{s}$ and $\underline{\hat{\sigma}}$ are congruent vectors formed from the nonredundant elements of the empirical (S) and model-implied ($\hat{\Sigma}$) covariance/correlation matrix of the

observed variables, and W is a consistent estimate of the asymptotic covariance matrix of the elements of S . This approach can be applied to SEM analysis with polychoric correlations if one can estimate W for polychoric correlations and then invert that matrix, as indicated. Applied in this way, this approach has been labeled *weighted least squares* (WLS) estimation.

Problems With the Weight Matrix

However, this application also proved to be problematic. The matrix W is large and the formula is complex. With k observed variables in the structural equation model, W is a square matrix of dimension $k * (k + 1)/2$. This large matrix must be not only estimated but also successfully inverted. Simulation studies have shown this approach to SEM analysis yields stable results only when sample size is very large. Smaller sample sizes (such as those seen in typical SEM applications) lead to implausible results or to outright estimation failure.

Researchers have described at least two approaches to overcome problems with this WLS approach. One alternative is to estimate the asymptotic covariance matrix empirically through bootstrapping. In a simulation study, this alternative performed well for a model with 15 variables at a sample size of 500. A second alternative, labeled *robust weighted least squares* or *diagonally weighted least squares*, avoids the inversion problem by, in essence, replacing the WLS weight matrix, W , with an alternative weight matrix that does not require inversion and whose estimate is stable at substantially lower sample sizes. In simulations, this procedure performed at least as well as the WLS approach and provided acceptable results for small models at sample sizes as low as 200. Violations of the assumption of underlying normality had little effect on the results obtained from either WLS or robust WLS.

Alternative Approaches for Ordinal Data

Nevertheless, recent research posits a number of alternative approaches for factor analysis of ordinal variables that do not involve the polychoric correlation coefficient. One approach, for example, simultaneously estimates thresholds and factor loadings, with item correlations being inferred from the factor loadings. This approach shifts the focus from responses to individual ordinal variables to patterns of responses across the whole set of observed variables. The approach then maximizes the likelihood of observing the distribution of response patterns actually observed in the data, conditional on the specified factor model. This approach relies on the conditional independence of observed

variables given the factor model. Such alternative approaches may likely come to dominate structural equation modeling of ordinal data, limiting the use of the polychoric correlation coefficient for this purpose.

POLYNOMIALS

In social-behavioral sciences, the term *polynomial* concerns the use of exponents or special coefficients to assess trends in linear models, with applications in ordinary least squares (OLS) regression, general linear model (GLM) analysis of variance (ANOVA), and other advanced multivariate applications such as hierarchical linear modeling, logistic regression, and generalized estimating equations. In more formal mathematics, polynomials are algebraic expressions that include exponents and have other specific properties. The simplest case of a polynomial is the OLS linear regression equation $Y = A + bX^1$ (in OLS regression, X^1 is typically represented as

X). One of the earliest examples of polynomials to assess trends can be traced to Karl Pearson's 1905 work addressing "skew correlation," where he used an exponential approach to assess nonlinear association.

The following discussion addresses the use of powered polynomials in OLS regression and orthogonal polynomials derived from special coefficients in both OLS regression and GLM ANOVA (these approaches may be used in other multivariate analyses as well). Both nonorthogonal and orthogonal polynomials are also discussed.

Polynomials can take the form of powered coefficients in OLS linear equations used for trend analysis. The linear equation of $Y = A + b_1X + b_2X^2$ illustrates the use of *powered polynomials*, with b_1X as the linear term (not shown is X taken to the first power), and the squared term b_2X^2 producing a quadratic term. When powered polynomials are used for trend analysis, the resulting trends are nonorthogonal, meaning nonindependent. When the trends are created using powered polynomials, the quadratic and higher order terms are built from the linear term (for example, X is used to create X^2), and thus are highly correlated. To make the terms orthogonal (i.e., independent), the data require mean-centering as noted by Patricia Cohen, Jacob Cohen, Stephen G. West, and Leona S. Aiken. Otherwise, hierarchical regression is used in assessing the trends to account for nonorthogonality.

Orthogonal polynomials are formed through special coefficients called *coefficients of orthogonal polynomials*, a term used by William Hays, and are provided in most advanced statistics textbooks. They are constructed to be independent of each other. In using orthogonal polynomials for trend analysis, the derived linear and quadratic terms are independent of each other when the group or condition sizes are equal. If group or condition sizes are unequal, the resulting polynomials will not be orthogonal.

The special coefficients for orthogonal polynomials may be used in both OLS regression and GLM ANOVA designs. In regression, the orthogonal polynomial coefficients are used directly as predictor variables for each trend, whereas in ANOVA, the coefficients are used to multiply the group or condition mean values in a fashion similar to those used to assess planned comparisons.

An illustration using orthogonal polynomials in OLS regression is offered below. Assume Y is a behavioral outcome, and X is an ordered grouping variable with three levels representing drug dosage (1 = 0 mg, 2 = 10 mg, 3 = 20 mg). Each group has an n of 30 ($N = 90$). With three dosage levels, a linear and quadratic trend may be fit. Two sets of orthogonal polynomial coefficients taken from David C. Howell are applied to fit these trends: $-1 \ 0 \ 1$ for the linear trend; and $1 \ -2 \ 1$ for

the quadratic trend. In OLS regression, the resulting regression equation would be $Y = A + bX_{\text{linear}} + bX_{\text{quadratic}}$. The linear trend X_{linear} is formed by recoding the dosage variable using the orthogonal polynomial coefficients for the linear trend. Those receiving 0 mg of the drug are assigned “-1,” those receiving 10 mg are assigned “0,” and those with 20 mg of the drug are assigned “1.” The same is done for the quadratic trend $X_{\text{quadratic}}$, with those receiving 0 mg assigned “1,” those receiving 10 mg assigned “-2,” and those receiving 20 mg assigned “1.” If this analysis was performed in GLM ANOVA, the same orthogonal polynomial coefficients would be used as planned comparisons to repartition the treatment variance into linear and quadratic components.

POOLED VARIANCE

The pooled variance estimates the population variance (σ^2) by aggregating the variances obtained from two or more samples. The pooled variance is widely used in statistical procedures where different samples from one population or samples from different populations provide estimates of the same variance. This entry explains pooled variance, illustrates its calculation and application, and provides cautionary remarks regarding its use.

Estimate of Population Variance: One Sample Case

In usual research settings, researchers do not know the exact population variance. When there is only one

sample from a population, researchers generally use the variance of the sample as an estimate of the population variance. In the case of one sample, the formula to calculate the sample variance is

$$SD_2 = \frac{\sum (X_i - M)^2}{n - 1},$$

where X_i s are the observed scores in the sample, n is the sample size, and M and SD are the sample mean and standard deviation, respectively. This sample variance is an unbiased estimate of the population variance. In other words, the mean of variances of all possible random samples of the *same* size drawn from the population is equal to the population variance.

Pooled Variance

In many statistical procedures involving multiple groups, there are multiple sample variances that are independent estimates of the same population variance. For example, when samples from the same population are randomly assigned to two or more experimental groups, each group's variance is an independent estimate of the same population variance. In such a condition, the pooled variance is a more precise estimate of the population variance than an estimate based on only one sample's variance. Thus, the variances of all samples are aggregated to obtain an efficient estimate of the population variance.

In the case of k samples whose variances are independent estimates of the same population variance, the formula to calculate the pooled estimate of the population variance is

$$\frac{(n_1 - 1)SD_1^2 + (n_2 - 1)SD_2^2 + \cdots + (n_k - 1)SD_k^2}{(n_1 - 1) + (n_2 - 1) + \cdots + (n_k - 1)},$$

where $n_1, n_2, \dots, n_k$ are the sample sizes and $SD_1^2, SD_2^2, \dots, SD_k^2$ are the sample variances. To obtain the pooled estimate of the population variance, each sample variance is weighted by its degrees of freedom. Thus, pooled variance can be thought of as the weighted average of the sample variances based on their degrees of freedom.

Homogeneity of Variance

A common application of pooled variance is in statistical procedures where samples are drawn from different populations/subpopulations whose variances are assumed to be similar. In such conditions, each sample's variance is an independent estimate of the same population variance. When variances of samples that belong

to different (sub)populations are pooled to yield an estimate of the (sub)population variance, an important assumption is that the (sub)populations have equal variances ($\sigma_1^2 = \sigma_2^2 = \dots = \sigma_k^2$). This assumption is known as the *homogeneity of variance* assumption.

There are statistical tests to evaluate the tenability of the homogeneity of variance assumption, such as Levene's test or Bartlett's test. For these tests, the null hypothesis is that the population variances are equal. It is important to note that the null hypothesis refers to the population parameters. If the null hypothesis is not rejected (i.e., $p_{\text{calculated}}$ value $> \alpha$), the homogeneity of variance assumption holds, and the pooled estimate of the population variance can be used.

Example

A heuristic example is used to illustrate the calculation and application of pooled variance. Although the number of samples from which we obtain variance statistics will differ, steps used in this example for the pooled-variance calculation can be generalized to other situations. This example, which compares male and female students' reading scores using a t test, is provided to illuminate applications of pooled variance and processes underlying pooled-variance calculations. Therefore, some details about t tests are explained or elaborated.

The null (H_0) and alternative (H_a) hypotheses for this t test were stated as follows:

H_0 : The population means are the same ($\mu_1 = \mu_2$).

H_a : The population means are not the same ($\mu_1 \neq \mu_2$).

To test the H_0 , two independent samples, 41 female and 51 male students, were randomly chosen from the respective populations. In these samples, the mean reading score and standard deviations for females and males were $M_1 = 100$ ($SD_1 = 50$) and $M_2 = 80$ ($SD_2 = 45$), respectively. Thus, the samples have not only different means but also different variances in their reading achievement scores. Because the extent to which the means are good representatives of the scores in each sample depends on the dispersion of the scores (i.e., a mean better represents all the scores as the SD gets smaller), the dispersions of the scores logically must be taken into account in the comparison of the means.

The t statistic that is used to compare the means of two independent samples is derived using sampling distributions of the differences between two sample means. The formula for the statistic is

$$t = \frac{(M_1 - M_2) - (\mu_1 - \mu_2)}{SE_{M_1 - M_2}},$$

where $\mu_1 - \mu_2$ is the value stated in the null hypothesis (for our example, $\mu_1 - \mu_2 = 0$) and $SE_{M_1 - M_2}$ is the estimate of the standard error of the difference between sample means ($M_1 - M_2$).

The standard error of the difference between two sample means in the population ($\sigma_{M_1 - M_2}$) can be obtained using the formula

$$\sigma_{M_1 - M_2} = \sqrt{\sigma^2 \left(\frac{1}{n_1} + \frac{1}{n_2} \right)},$$

where σ^2 is the population variance, and n_1 and n_2 are sample sizes. It is important to note that to obtain $\sigma_{M_1 - M_2}$, the homogeneity of variance must be assumed (i.e., the variances of the two populations from which the samples are drawn are equal: $\sigma_1^2 = \sigma_2^2 = \sigma^2$). If the homogeneity of variance assumption is not met, $\sigma_{M_1 - M_2}$ can be obtained using adjusted formulas.

In typical research situations, $\sigma_{M_1 - M_2}$ is rarely known, so an estimate, $SE_{M_1 - M_2}$, is used. If the homogeneity of variance assumption is met, to get the $SE_{M_1 - M_2}$, σ^2 is replaced by SD_{pooled}^2 in the formula for $\sigma_{M_1 - M_2}$.

$$SE_{M_1 - M_2} = \sqrt{SD_{\text{pooled}}^2 \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}$$

In the formula for $SE_{M_1 - M_2}$, SD_{pooled}^2 is used as an estimate of the population variance. In our example, the sample variances for females and males were 2,500 and 2,025, respectively. Assuming that the population variances for females and males were the same, each of the sample variances is an independent estimate of the population parameter. Rather than using one of the sample variances as an estimate of the parameter, a more statistically efficient estimate is obtained by pooling the sample variances:

$$\begin{aligned} SD_{\text{pooled}}^2 &= \frac{(41-1)(50^2) + (51-1)(45^2)}{(41-1) + (51-1)} \\ &= 2,236.1. \end{aligned}$$

Thus, the pooled estimate of the population variance, which is a weighted average of the sample variances (i.e., $SD_1^2 = 50$ and $SD_2^2 = 45$ for females and males, respectively) based on their degrees of freedom ($df_1 = 40$ and $df_2 = 50$ for females and males, respectively), is 2,236.1.

When the SD_{pooled}^2 value is substituted in the formula of $SE_{M_1 - M_2}$,

$$SE_{M_1 - M_2} = \sqrt{(2,236.1) \left(\frac{1}{41} + \frac{1}{51} \right)} = 9.92$$

and accordingly,

$$t = \frac{(100 - 80) - 0}{9.92} = 2.02.$$

The t statistic is interpreted as a mean difference of 20 in the sample and is 2.02 standard deviations away from the hypothesized population mean difference, which is 0. Using a commonly available t statistic distribution, the p value for our two-tailed hypothesis test is approximately .046. At the .05 level of significance, we reject the H_0 , which stated that the reading scores for females and males in the population were the same.

In addition to t tests, pooled variances are commonly used as part of analyses of variance (ANOVAs). For example, when conducting an ANOVA to compare differences between students' mean reading scores by ethnicity, each ethnicity is a subgroup of the student population. To test differences of mean reading scores between ethnicities, an important assumption in ANOVA is that the variances between dependent variable scores in each ethnicity in the population are equal. Thus, a pooled estimate of the population variance is obtained by aggregating the sample variances from each ethnicity. ANOVA is somewhat robust to the violation of homogeneity of variance assumption, if group sizes are equal, so in many cases, a pooled variance is acceptable even if the variances in the populations are not considered exactly equal.

Careful Use of Pooled Variances

Introductory statistics courses typically introduce parametric methods, which have more assumptions about the data than nonparametric methods. For example, parametric assumptions for a t test for comparing two means are that (a) data have been randomly chosen from the population, (b) the population data are normally distributed, and (c) the variances in the two populations are equal (i.e., homogeneity of variance). When these assumptions are met, parametric methods produce accurate results and the t statistic would be computed with the pooled variance and evaluated with $n_1 + n_2 - 2$ degrees of freedom. However, as the variances in the two samples diverge, the better choice would be to use the unpooled variance along with the appropriate degrees of freedom.

In the case of the t test, unpooled variances would be used if the t test assumptions were not met. The unpooled variance equals the sum of the variances divided by the sample size for each of the two samples. When sample sizes of the two groups are equal, the pooled and unpooled variances are equivalent. The impact of using the pooled or unpooled variance is

affected by small sample sizes and whether or not the larger variance is associated with the smaller or larger sample size.

When parametric assumptions are met and sample sizes are not equal, the absolute value of the t statistic will be slightly higher when the unpooled variance is used. The higher t statistic corresponds to a higher likelihood of rejecting the null hypothesis and an inflated risk of committing a Type I error (i.e., rejecting a true hypothesis). There has been some discussion of using the unpooled variances more often, and the interested reader can consult the Further Readings section to find out more about that discussion.

POPULATION

With respect to research design and statistical analysis, a *population* is the entire collection of entities one seeks to understand or, more formally, about which one seeks to draw an inference. Consequently, defining clearly the population of interest is a fundamental component of research design because the way in which the population is defined dictates the scope of the inferences resulting from the research effort.

When a population is small, it can be censused, meaning that the attribute of interest is measured for every member of the population and is therefore known with certainty. More often, however, a census is

unrealistic because the population is not finite or because financial or logistical constraints override collection of complete information. In some cases, simply redefining the population may permit a census, perhaps by reducing the size or extent of the population of interest. When a census is still not feasible or when complete information about a population is unnecessary, a subset of the defined population called a *sample* is selected and measured. Attributes of the sample are used to make inferences about the entire population from which the sample was drawn. Statistical tools make use of these inductive inferences, using specific cases (the samples) to generalize or make inferences about the whole (the population). Specifically, a sample statistic provides an estimate of the population parameter, the true value of the attribute of interest. As George Snedecor and William Cochran wrote, it is the sample we observe, but the population we wish to know.

Such inductive inferences will be valid when the sample is drawn using an approach that ensures each unit of the population has a chance to be selected as part of the sample, such as a probabilistic sampling scheme, and inferences are restricted to the entities of the population that were available for sampling. For example, if data on test scores were collected from a random sample of undergraduate students enrolled in a specific calculus course at a single university, inferences apply only to that course and university and not to all undergraduates, all math courses, or all universities. If a researcher was interested in drawing general conclusions about current test scores in undergraduate calculus courses throughout the United States, undergraduate students currently enrolled in all calculus courses at universities across the United States must be available for selection as part of the random sample. This example emphasizes the importance of defining the population of interest explicitly when designing a sampling scheme because of its overriding importance on inference.

POSITIVISM

Positivism is the name of a philosophical doctrine created in France by Auguste Comte. As a term of research in human sciences, *positivism* has come to be closely associated with the idea of fact-based investigation, being a pejorative variation of *empiricism*. This entry discusses the various definitions and applications of positivism.

Definitions

When *positivism* as a term is used in the history of historiography, it tends to refer to the work of scholars in the Third Republic in France; *positivistic historians* in this context means scholars who produced historical research that followed a rigorous method of systematic investigation of sources (what historians of the Annales school pejoratively called *histoire historisante*). In social sciences, *positivism* has become a synonym for a rejection of metaphysics and a heightened concern for observable and measurable phenomena in the natural and social world. Likewise, in language studies, the term *positivism* has come to mean a failed attempt to compare and transplant methods of physical sciences to the realm of human language-based communication. Until recently, in all these cases, when the word *positivism* is used, it was normally used in a negative sense to allow for criticism of the approach or method in question (Karl Popper having been one of the main opponents of Comte's philosophy of science in the 20th century).

The word *positivism* was incorporated into the vocabulary of human sciences, and it currently has different meanings for modern scholars. Georg Iggers claimed that positivism means a belief that historical facts are self-explanatory and do not require mediation of hypothesis, interpretation, or operational definitions. Wilson Simon claimed that only Comte's positivism could truly be called by that name, as it was based on a personal conviction that human behavior could be examined using the same laws of physical and natural sciences. Donald Charlton, Norman Cantor, and Richard Schneider promoted the idea of positivism replaced

with a “scientific nominalism,” meaning textual criticism and hostility to hidden meaning and interpretation was a more apt term than positivism. For William Keylor, positivism means a theory of fact-oriented science.

Applications

Any initial definition of the term *positivism*, however, should relate it to Comte’s work. Comte’s oeuvre sought to establish an understanding of how humanity had evolved from the first stage of its development (theological) to the second (metaphysical) and would further progress until it finally reached its most perfect state (the positive stage). Positivism—or *science positive*—is Comte’s ambitious attempt to synthesize all the conflicting philosophies of his time through a new philosophy of history capable of explaining human experience as a function of the development of the human mind. Through this and through the epistemological assumption that only through direct observation can knowledge be attained, Comte envisioned human history in somewhat utopian terms as culminating in a flawlessly well-integrated society. In order to capture all of human experience (historical, social, political, and intellectual), Comte founded the science of sociology.

Combining “social positivism” (the science that studied the human race, focusing on the social relationships between individuals); the “religion of humanity” (the ethical, nontheistic religion based on the collective and the individual aspects of humankind); and a theory of knowledge (based on the assumption that humans evolve from the theological stage into the metaphysical one and then to the positive one, not yet fully achieved), positivism forms the basis of modern science, at which stage science gains supremacy over philosophy (or metaphysics). In this context, positivism can be seen as an attempt to incorporate and improve the pre-19th-century theories of knowledge, which based some or all of their arguments on a priori knowledge and relied upon metaphysical, religious, or moralistic assumptions, not simply on material reality. The purpose of Comte’s work was to offer a satisfactory explanation for the crisis in French politics and society, which had started with the French Revolution in 1789, and to suggest that by understanding social phenomena, one could understand political occurrences and, as a result, start the process of social reconstruction that would eventually eliminate politics from society.

Positivism entered the debates of politicians, academics, and others in the 1850s, becoming dominant, at least in France, by the 1860s. The positivism to which these groups referred was not always Comtean positivism. Comte’s positivism as applied to social

sciences (he actually coined the term *sociology*, capturing his life’s goal of understanding human experience) was a system based on an understanding of the world and humankind founded on the principle of an analogy between the elements of the human world (complex phenomena of language, social life, and human thought) and those of the natural world (simple phenomena of inorganic and organic nature). In Comte’s system, the analogy between humans and nature allowed the scientist to apply the methods of the positive sciences (biology, physics, and chemistry) to the humanities. In particular, the use of Comte’s law of three stages of humanity, whereby societies could evolve from one less developed stage to another, more developed stage, was an essential part of 19th-century philosophy of history, which, although incorporating the works of some like Condorcet (Comte’s spiritual father, from whom he learned the idea of organic development of human history in 10 stages), largely rejected the Whiggish/Enlightenment-based idea of history as a linear progression as opposed to a series of developmental stages. The development-based approach perfected by Comte clearly influenced many 19th-century thinkers, including John Stuart Mill and Karl Marx. For both Comte and Marx, the political system reflected civil order, this in turn reflecting the state of civilization.

An element of Comte’s philosophy that was appropriated by scholars in the second half of the 19th century was the claim that education was the basis for social development because it was capable of regenerating society. Comte’s pedagogical claims are varied, mostly opposing the humanist-type education (which valued rhetoric and the power of language) and focusing on clarity, objectivity, and conciseness. In Comtean philosophy, the study of facts is essential because facts are morally charged. Consequently, the investigation of facts has the capacity of social transformation. The need is, therefore, to ensure that facts were learned the appropriate way and according to pupils’ developmental stage. Comte posited an analogy between the mental development of individuals and that of humanity, so that the individual’s education progresses through the same intellectual/emotional stages as humanity has progressed through history, until it finally reaches the positive stage. This formulation and its uses by educators were particularly important because of its pedagogical implications and applications (exemplary cases of the development of positivistic-based pedagogy were developed in India, Brazil, Mexico, Guatemala, and Argentina, as well as France itself), extending in time, in some cases, to the post–World War II period.

Aside from sociology and pedagogy, positivism had a short but powerful application to French politics. Comtean positivism was, by nature, authoritarian,

hierarchical, and antidemocratic, based on a reactionary view that was intended as a means to guarantee a non-violent political environment and the realization of social perfection through peaceful means. Comte acknowledged himself as a follower of Joseph de Maistre and Louis de Bonald, both of whom were counter-Revolutionary thinkers who claimed that there was no need for violent revolution to change society. This view generally has been accepted, although some revisionist work has sought to demonstrate that many of the followers of Comte aimed to use positivism in their creation of liberal and democratic institutions. It is undeniable, however, that the aims of Comte himself were far from liberal and democratic. Order and progress were the tenets of the project that would eventually implement a positive society. This was accomplished via a series of highly complex scientific and emotional/religious processes whereby wisemen were responsible for educating the lower classes and establishing a republic of knowledge.

In France, positivism came to be associated with republicanism, in particular during the latter years of the Second Empire and the dawn of the Third Republic. Sudhir Hazareesingh suggests that the republican interpretation of Comte's positivism was offered by Émile Littré, a disciple of Comte and an early enthusiast of his master's version of positivism. It was through him that the Comtean doctrine was liberalized and republicanized, thus losing its affiliation to its creator and becoming a philosophy in and of itself; some of the European variations of positivism are clearly Littréan. Littré wrote *Conservation, Revolution, Positivism* in 1852 to recover the idea that positivism could have a socially and politically transformative character as long as it became clear that under a centralized government such as that which the Second Empire was shaping up to be, there could be no unified science and no hope for progress. What Littré passed on to republicans like Third Republic figures Léon Gambetta and Jules Ferry was the idea that one can create order from disorder, as Comte had advocated, but scientific progress was possible only under a republic. In order for there to be a republic, there should be democracy, and in order for there to be democracy, socialized (mass) education was necessary.

In Latin America, however, the positivism that influenced governments in the late 19th century was hardly the democratic-Littréan variation, but rather the authoritarian and conservative Comtean positivism, as is clear in the cases of Brazil, Mexico, Argentina, and Guatemala. In any event, the political application of positivism sought to legitimize a strong state and to focus on mass education as a means to guarantee adherence to the status quo, as Leopoldo Zea claimed.

The influence of positivism in politics and pedagogy was indeed felt for nearly a century in Europe and abroad. As a philosophy of science and a research methodology, however, the supremacy of positivism was short-lived. By the end of the 19th century, positivism, as a methodology for human sciences, had fallen into disrepute. Linguists and philologists became increasingly suspicious of the mixture of physical and human sciences as regards their methodology. Sociologists felt the same, and even historians started disclaiming theories that linked the process of knowing rocks as described by geologists to the process of knowing human beings as sought by historians, as Charles-Olivier Carbonell has noted. Nonetheless, there were attempts to recover Comtean positivism as a methodology for human sciences in the late 19th century, especially as the process of secularization of French society and politics was under way. Denying the current state of institutionalized religion, positivism's erasure of free will, and Christian providentialism in favor of a deterministic and accident-based approach (as Raymon Aron suggested), at least as a label, positivism still portrayed itself as a methodological guarantor of the scientific rigor of historical studies and had fulfilled its role.

Debates about positivism in historical studies and human sciences in general had one effect: In the desire to show their usefulness for society, human sciences (and their scholars) attempted to help themselves by establishing a link between democracy, liberalism, and liberal arts. History, which was once seen as a mildly conservative discipline in the sense of pointing to alternatives to drastic social change, became the herald of a new order. Sociology, too, by reinterpreting positivism via the work of Émile Durkheim, established itself as a discipline (also of slightly conservative tendencies) in Paris and then other European nations thanks to positivism.

The sound bites of positivism are varied and can be found in numerous sources that contend, dismiss, and detract positivism and the aims of its conceptual creator: the need for objectivity and an empirical approach to facts; the lack of need to look for final causes for historical facts; an understanding that facts are morally charged and, as a result, capable of transforming politics and society; the predictive ability of science in terms of pointing to patterns of human behavior; and the need to use direct observation in order to accrue knowledge (in the case of past knowledge, empirical use of documentary sources, mostly literary), in addition to the moral need to educate the politically enabled populace. They point to the variety of ways in which positivism was employed (and is still employed) in politics, epistemology, and moral philosophy.

Post Hoc Analysis

Post hoc analysis applies to tests of differences among sample statistics when the specific hypothesis to be tested has been suggested by the values of the statistics themselves. Perhaps the most common statistic to be tested is the sample mean in experiments involving three or more means. In such cases, it is most common to begin with the testing of an analysis of variance (ANOVA) F test. A nonsignificant F test implies that the full null hypothesis of the equality of all population means is plausible. Consequently, no additional testing would be considered.

Suppose a significant ANOVA F test is found in an experiment involving $k = 4$ means. If the last two means are greater than the first two means, a researcher might want to know if that difference would also be found in comparing the corresponding population means. That researcher would be interested in testing the hypothesis

$$H_0 : \frac{\mu_1 + \mu_2}{2} = \frac{\mu_3 + \mu_4}{2}.$$

Equivalent hypotheses would be

$$H_0 : \mu_1 + \mu_2 - \mu_3 - \mu_4 = 0$$

or

$$H_0 : \psi = 0$$

where ψ represents the ordered coefficients (1, 1, -1, -1) applied to the corresponding four population means. In general, any contrast among four means could be expressed by the four ordered coefficients (c_1, c_2, c_3, c_4).

To test the hypothesis using the four sample means, ψ is estimated by applying the four coefficients to the corresponding sample means to calculate Y as

$$Y = c_1M_1 + c_2M_2 + c_3M_3 + c_4M_4.$$

For equal sample sizes with common value, N , a corresponding sum of squares is obtained by

$$SS_Y = NY_2 / c_i^2.$$

For unequal sample sizes, $N_1, N_2, \dots, N_k$, the formula is

$$SS_Y = \frac{Y^2}{\sum_{i=1}^k \frac{c_i^2}{N_i}}.$$

The contrast has $df = 1$, so dividing by 1 (i.e., keeping the same value) changes the SS_Y to a mean square, MS_Y . If the contrast had been chosen without first examining the sample means (especially if it was chosen before the experiment was performed), then it would be an a priori contrast rather than a post hoc contrast. In that case, an F test for the contrast, F_Y , is calculated by

$$F_Y = \frac{MS_Y}{MS_{\text{error}}},$$

where MS_{error} is the denominator of the ANOVA F test. The critical value would be obtained from an F distribution with 1 and df_{error} degrees of freedom.

For post hoc analysis, Henry Scheffé provided a similar method for testing the contrast hypothesis. For a contrast among k means, the MS_Y is

$$MS_Y = \frac{SS_Y}{k-1}.$$

The critical value is obtained from an F distribution with $k-1$ and df_{error} degrees of freedom. If the critical value is determined with a significance level, α the probability of one or more Type I errors will be limited to α no matter how many contrasts are evaluated as post hoc contrasts by the Scheffé procedure. In fact, Scheffé even proved that if the ANOVA F test is significant, then at least one post hoc contrast must be significant by the Scheffé procedure.

Scheffé's procedure can be used for testing hypotheses about any number of means in a contrast. However,

pairwise testing of only two means at a time can be done with more powerful procedures. John Tukey proposed a single, critical difference, CD, for all pairs of means in a group of k means each with sample size N . That value is

$$CD = q_{1-\alpha}(k, df_{\text{error}}) \sqrt{\frac{MS_{\text{error}}}{N}},$$

where $q_{1-\alpha}(k, df_{\text{error}})$ is the 100(1 - α) percentage point of the Studentized range distribution with parameters k and df_{error} . Tukey's procedure limits the probability of one or more Type I errors to α even when testing all $k(k - 1)/2$ pairs of k means and even if the ANOVA F test is *not* significant. However, it is almost a universal practice to apply Tukey's procedure only after a significant ANOVA F test.

With unequal sample sizes N_i and N_j , Tukey's procedure is modified to become the Tukey–Kramer procedure where CD is given by

$$CD = q_{1-\alpha}(k, df_{\text{error}}) \sqrt{\frac{MS_{\text{error}}}{2} \left[\frac{1}{N_i} + \frac{1}{N_j} \right]}.$$

The Tukey–Kramer procedure also limits the probability of one or more Type I errors to α even when testing all $k(k - 1)/2$ pairs of k means and even if the ANOVA F test is not significant. However, it is also almost a universal practice to apply the Tukey–Kramer procedure only after a significant ANOVA F test.

A. J. Hayter proposed a modification of Fisher's least significant difference procedure that can be considered a powerful variation on Tukey's procedure. For equal N , the Hayter–Fisher CD becomes

$$CD = q_{1-\alpha}(k - 1, df_{\text{error}}) \sqrt{\frac{MS_{\text{error}}}{N}}.$$

The only change from Tukey's CD formula is to replace the parameter k with $k - 1$. This makes the CD value for the Hayter–Fisher procedure always smaller than the CD for Tukey's procedure. However, the Hayter–Fisher procedure always requires a significant ANOVA F test before applying the CD to pairwise testing. For pairwise testing of exactly three means, each based on the same size, N , and following a significant ANOVA F test, there is no procedure more powerful than the Hayter–Fisher when the usual ANOVA assumptions are satisfied.

For unequal N , the Hayter–Fisher uses the formula

$$CD = q_{1-\alpha}(k - 1, df_{\text{error}}) \sqrt{\frac{MS_{\text{error}}}{2} \left[\frac{1}{N_i} + \frac{1}{N_j} \right]}.$$

Again, the only change from the Tukey–Kramer is replacing k with $k - 1$.

For $k > 3$ means, a procedure more powerful than the Hayter–Fisher is the Peritz procedure. The procedure involves following a significant ANOVA F test with additional F tests for all possible tests of null conditions of partitions of the k means. The procedure is illustrated in the example below.

The statistical literature provides a large number of alternative procedures for post hoc testing. However, the few procedures presented here can be used in many cases. To avoid the ANOVA assumption of equal population variances, the Peritz F tests can be replaced by the Brown and Forsythe procedure as modified by D. V. Mehrotra.

Illustrative Example

Alizah Z. Brozgold, Joan C. Borod, Candace C. Martin, Lawrence H. Pick, Murray Alpert, and Joan Welkowitz reported a study of marital status for several psychiatric groups and normal controls with high scores indicating *worse* marital status. The summary statistics for four groups were as follows:

Group 1	Group 2	Group 3	Group 4		
<i>Right Brain Damaged</i>	<i>Normal Controls</i>	<i>Unipolar Depressives</i>	<i>Schizophrenics</i>		
RBD	NC	UD	SZ		
$M_1 = 1.22$	$M_2 = 1.50$	$M_3 = 3.00$	$M_4 = 4.61$		
$s_1 = 1.93$	$s_2 = 1.79$	$s_3 = 1.91$	$s_4 = 1.69$		
$N_1 = 19$	$N_2 = 21$	$N_3 = 12$	$N_4 = 20$		
<i>Source of Var.</i>	<i>SS</i>	<i>df</i>	<i>MS</i>	<i>F</i>	<i>p Value</i>
Treatment	144.076	3	48.026	14.48*	<.0001
Within Groups	225.556	68	3.317		
Total	3369.633	71			

* $p < .05$. Reject H_0 because $14.48 > 2.75 = F_{.95}(3,68) > F_{.95}(3,68) = CV$.

Table 1 presents the CD values for the Scheffé, Tukey–Kramer, and Hayter–Fisher procedures. As expected, the Scheffé is least powerful for pairwise testing, showing only two differences as significant. In this case, the Right Brain Damaged have significantly better marital status than the Schizophrenics. The Tukey–Kramer is more powerful, showing three differences as

Table 1 Six Pairwise Differences Tested for Significance by Three Procedures

Pair	Group <i>i</i>	Group <i>j</i>	Diff.	Scheffé-CD	TK-CD	HF-CD
1	1.22	1.50	.25	1.65	1.50	1.37
2		3.00	1.78	1.93	1.75*	1.60*
3		4.61	3.39	1.67*	1.52*	1.35*
4	1.50	3.00	1.50	1.89	1.71	1.57

significant. That is, the Tukey–Kramer also finds significantly better marital status for the Right Brain Damaged than the Unipolar Depressives. Finally, the most powerful of the three is the Hayter–Fisher, with four significant differences. The Hayter–Fisher finds the Unipolar Depressives to have significantly better marital status than the Schizophrenics.

Table 2 presents the *F* tests required by the Peritz procedure that are needed to determine the significance of the difference between Means 2 and 3 (i.e., $M_2 = 1.50$ and $M_3 = 3.00$). This pair of means was not

significantly different in Table 1. The first partition is actually no partition at all because it includes all four means. The *F* test is the overall ANOVA *F* test and is significant as noted above. The second partition includes the first three means in one group, and Mean 4 is a second group. The hypothesis is that the first three population means are equal, and the $F = 3.83$ is significant at $\alpha = .05$ so the hypothesis is rejected. The third partition assigns M_1 and M_4 to one group and M_2 and M_3 to a second group. Both groups are tested for a significant difference at $\alpha = .0253$. Only one need be

Table 2 Pairwise Testing With the Peritz Procedure Applied to Means $M_2 = 1.50$ and $M_3 = 3.00$

		<i>M1</i>	<i>M2</i>	<i>M3</i>	<i>M4</i>		
Partition	Hyp.	1.22	1.50	3.00	4.61	<i>F</i>	<i>F_{CV}</i>
1		1	1	1	1		
	1	1	1	1	1	14.48	2.74
2		1	1	1	2		
	1	1	1	1		3.83	3.13
3		1	2	2	1

4		1	2	2	2		
	1		2	2	2	14.94	3.13
5		1	2	2	3		
	1		2	2		5.18	3.98

significant for the Peritz procedure to find M_2 and M_3 to differ significantly. The fourth partition assigns M_1 to one group and M_2 , M_3 , and M_4 to a second group. The hypothesis is that the last three population means are equal. This hypothesis is also significant at $\alpha = .05$. Finally, the fifth partition assigns M_1 to one group, M_2 and M_3 to a second group, and M_4 to a third group. This partition tests the simple hypothesis that the second and third population means are identical. This test is significant at $\alpha = .05$. The five partitions shown in Table 2 include all partitions in which M_2 and M_3 are included together in the same group. A significant test must be found for all five partitions.

The additional significant pair found by the Peritz procedure illustrates its greater power than the other three procedures. The Normal Controls are shown to have significantly better marital status than the Unipolar Depressives.

The entire Peritz procedure requires the same type of testing shown in Table 2 applied to all six pairs of means. The Peritz procedure identifies five of the six pairs to be significantly different. The Peritz procedure will generally (but not always) be more powerful than the Hayter–Fisher procedure for $k \geq 4$. Clearly, this procedure requires a computer program to be practical.

Post Hoc Comparisons

Post hoc comparisons, or *a posteriori analyses*, typically refer to pairwise mean comparisons after a significant analysis of variance (ANOVA). The F test used in analysis of variance is called an *omnibus* test because it can detect only the presence or the absence of a global effect of the independent variable on the dependent variable. However, in general, we want to draw specific conclusions from the results of an experiment. Specific conclusions are derived from focused comparisons, which are, mostly, implemented as contrasts between experimental conditions. These comparisons are performed after an ANOVA has been performed on the experimental data of interest. In the ANOVA framework, post hoc analyses take two general forms: (a) comparisons that involve all possible contrasts and (b) comparisons that are restricted to comparing pairs of means (called *pairwise comparisons*).

Notations

The experimental design is a one-factor ANOVA. The total number of observations is denoted N , with S denoting the number of observations per group. The number of groups is denoted A , a given group is labeled with the letter a , the group means are denoted M_{a+} , and the grand mean is denoted M_{++} . A contrast is denoted ψ_a , and the contrast coefficients (contrast weights) are denoted C_a . The α -level per comparison is denoted $\alpha[PC]$ and the α -level per family of comparisons is denoted $\alpha[PF]$.

Planned Versus Post Hoc Comparisons

Planned (or *a priori*) comparisons are selected before running the experiment. In general, they correspond to the research hypotheses. Because these comparisons are planned, they are usually few in number. In order to avoid an inflation of the Type I error (i.e., declaring an effect significant when it is not), the p values of these comparisons are corrected with the standard Bonferroni or Šidák approaches.

In contrast, post hoc (or *a posteriori*) comparisons are decided after the experiment has been run and analyzed. The aim of post hoc comparisons is to make sure that (unexpected) patterns seen in the results are reliable. This implies that the actual family of comparisons consists of all possible comparisons, even if they are not explicitly tested.

Contrast

A contrast is a prediction precise enough to be translated into a set of numbers called contrast coefficients

Figure 1 (a) Appropriate Context (b) Partial Context for Bransford and Johnson's (1972) Experiment

Source: Reprinted from *Journal of Verbal Learning and Verbal Behavior*, 11, Bransford, J. D. Contextual prerequisites for understanding: Some investigations of comprehension and recall, 717-726, Copyright 1972, with permission from Elsevier. <https://www.sciencedirect.com/journal/journal-of-verbal-learning-and-verbal-behavior>

or contrast weights (denoted C_a) that express this prediction. For convenience, contrast coefficients have a mean equal to zero. The correlation between the contrast coefficients and the values of the group means quantifies the similarity between the prediction and the results.

All contrasts are evaluated using the same general procedure. A contrast is formalized as a set of contrast coefficients that represents the predicted pattern of experimental results. For example, if we have four groups and we predict that the first group should have better performance than the other three groups, and that these remaining three groups are equivalent, we get the following contrast:

$$\begin{array}{ccccc} C_1 & C_2 & C_3 & C_4 & \text{Mean} \\ \psi = 3 & -1 & -1 & -1 & 0 \end{array} \quad (1)$$

When the data have been collected and the experimental means and mean squares have been computed, the next step is to evaluate if the contrast correlates significantly with the mean values. In order to do so, a specific F ratio (denoted F_ψ) is computed. Finally, the probability associated with F_ψ is evaluated. If this probability is small enough, the contrast is considered significant.

Example

This example is a fictitious replication of Bransford and Johnson's 1972 study examining the effect of context on memory. In this study, Bransford and Johnson read the following paragraph to their participants:

If the balloons popped, the sound would not be able to carry since everything would be too far away from the correct floor. A closed window would also prevent the sound from carrying since most buildings tend to be well insulated. Since the whole operation depends on a steady flow of electricity, a break in the middle of the wire would also cause problems. Of course the fellow could shout, but the human voice is not loud enough to carry that far. An additional problem is that a string could break on the instrument. Then there could be no accompaniment to the message. It is clear that the best situation would involve less distance. Then there would be fewer potential problems. With face to face contact, the least number of things could go wrong.

To show the importance of context on memory for texts, the authors used the following four experimental conditions:

1. *No context*: Participants listened to the passage and tried to remember it.
2. *Appropriate context before*: Participants were provided with an appropriate context (see Figure 1a) in the form of a picture and then listened to the passage.
3. *Appropriate context after*: Participants first listened to the passage and then were provided with an appropriate context (see Figure 1a) in the form of a picture.
4. *Partial context*: Participants were provided with a context that did not allow them to make sense of the text when they listened to it (see Figure 1b).

The dependent variable is the number of "ideas" recalled. The data are shown in Table 1, and the results of the ANOVA are shown in Table 2.

Post Hoc Comparisons

Scheffé Test

When a post hoc comparison is performed, the family of comparisons consists of all possible comparisons. This number is, in general, very large, even when dealing with a small number of experimental conditions, and this large number practically precludes using a Bonferroni approach to correct for multiple testings because this large number of comparisons would make the correction much too conservative. The Scheffé test is also

Table 1 Number of Ideas Recalled for 20 Subjects in the Fictitious Replication of Bransford and Johnson (1972)

	Context Before	Partial Context	Context After	No Context
	5	5	2	3
	9	4	4	3
	8	3	5	2
	4	5	4	4

conservative, but less than the Bonferonni approach. The idea behind the Scheffé test begins with the omnibus F testing the null hypothesis that all population means are equal, and this null hypothesis in turn implies that all possible contrasts are also zero. Note that testing the contrast with the largest sum is equivalent to testing all possible contrasts at once (because a failure to reject the null hypothesis with the largest contrast implies a failure to reject the null hypothesis for any smaller contrast).

Suppose that Bransford and Johnson wanted to test the following four contrasts *after* having collected their data: (a) no context versus all other conditions, (b) context after versus no context, (c) context before versus all other conditions, and (d) context before versus partial context. The contrast weights (i.e., C_a s) are shown in Table 3.

The F_ψ ratio for the maximum contrast ψ_a is equal to

$$F_\psi = \frac{SS_\psi}{MS_{\text{error}}} = \frac{SS_{\text{between}}}{MS_{\text{error}}} = \frac{(A-1)MS_{\text{between}}}{MS_{\text{error}}} \quad (2)$$

$$= (A-1)F_{\text{omnibus}}$$

	Context Before	Partial Context	Context After	No Context
ψ_1	1	1	1	-3
ψ_2	0	0	1	-1
ψ_3	3	-1	-1	-1
ψ_4	1	-1	0	0

Source: Adapted from Bransford and Johnson (1972).

To have the Scheffé test contrast equivalent to the omnibus test, we need to reject the null hypothesis under the same conditions as the omnibus test. To reject the omnibus null hypothesis, F_{omnibus} must be greater than or equal to $F_{\text{critical, omnibus}}$. Because F is equal to $(A-1)F_{\text{omnibus}}$, then we reject the null hypothesis when

$$(A-1)F_{\text{omnibus}} > (A-1)F_{\text{critical, omnibus}} \quad (3)$$

and, therefore,

$$F_\psi > (A-1)F_{\text{critical, omnibus}} \quad (4)$$

Consequently, the critical value to test all possible contrasts is

$$F_{\text{critical, Scheffé}} = (A-1)F_{\text{critical, omnibus}} \quad (5)$$

with

$$v_1 = A - 1 \quad \text{and} \quad v_2 = A(S - 1) \quad (6)$$

degrees of freedom. For our example, $F_{\text{critical, Scheffé}}$ is equal to

$$F_{\text{critical, Scheffé}} = (A-1)F_{\text{critical, omnibus}} \\ = (4-1) \times 3.24 = 9.72 \quad (7)$$

with $v_1 = A - 1 = 4 - 1 = 3$ and $v_2 = A(S - 1) = 4(5 - 1) = 16$. An alternative approach is to correct the value of F by dividing it by $(A - 1)$ and evaluating its probability according to a Fisher distribution with $(A - 1)$ and $A(S - 1)$ degrees of freedom (i.e., the number of degrees of freedom of the omnibus test).

The results of the Scheffé test for the contrasts in Table 3 are shown in Table 4. The third contrast, ψ_3 , context before versus all other contexts, is the only significant contrast ($F_{\psi_3} = 19.92$, $p < .01$). This shows that memorization is facilitated only when the context information is presented before learning.

Table 4 The Results of the Scheffé Test for the Contrasts in Table 3

ψ_4	19.60	8.34	.0748	ns

Pairwise Comparisons

Honestly Significant Difference Test

The honestly significant difference (HSD) test is a conservative test that uses Student's q statistics and the Studentized range distribution. The range is the number of groups falling between groups (including the groups under consideration). For example, in the Bransford and Johnson experiment, the range of means between the largest and the smallest means is equal to 4 because there are four means going from 7.0 to 3.0 (i.e., 7.0, 4.2, 3.2, and 3.0).

To begin the HSD test, all pairwise differences are computed. These differences are shown in Table 6 for the Bransford and Johnson example. If the difference between two means is greater than the honestly significant difference, then the two conditions are significantly different at the chosen alpha level. The HSD is computed as

$$|M_{a+} - M_{a'+}| > \text{HSD} \\ = q_{A,\alpha} \sqrt{\frac{1}{2} MS_{\text{error}} \left(\frac{1}{S_a} + \frac{1}{S_{a'}} \right)} \quad (8)$$

with a range equal to A and $v = N - A$ degrees of freedom. For the Bransford and Johnson example, the HSD values are

$$\text{HSD}_{A,\alpha} = \text{HSD}_{4,\alpha=.05} = 2.37$$

for $p = .05$, and

$$\text{HSD}_{A,\alpha} = \text{HSD}_{4,\alpha=.01} = 3.59$$

for $p = .01$ with a range equal to $A = 4$ and $v = N - A = 20 - 4 = 16$ degrees of freedom. Using HSD, there are significant pairwise differences between the "context before" condition and the "partial context," "context after," and "no context" conditions.

Newman-Keuls Test

The Newman-Keuls test is a sequential test in which q_{critical} depends on the range of each pair of means. The

Table 5 Honestly Significant Difference Test

	Context Before	Partial Context	Context After	No Context
	$M_{1+} = 7.0$	$M_{2+} = 4.2$	$M_{3+} = 3.2$	$M_{4+} = 3.0$
$M_{1+} = 7.0$		2.8**	3.8**	4.0**
$M_{2+} = 4.2$			1.0	1.2
$M_{3+} = 3.2$				0.2

Notes: Pairwise differences between means for the Bransford and Johnson example. Differences greater than 2.37 are significant at the $p = .05$ level and are indicated by *. Differences greater than 3.59 are significant at the $p = .01$ level and are indicated by **.

Newman-Keuls test is the most popular a posteriori pairwise comparison test.

The Newman-Keuls test starts by computing the value of Student's q_{observed} for the largest pairwise difference:

$$q_{\text{observed}} = \frac{M_{a+} - M_{a'+}}{\sqrt{MS_{\text{error}} \left(\frac{1}{S} \right)}} \quad (9)$$

(where a and a' are respectively the smallest and the largest means). This value is then evaluated with a Studentized distribution with a range of A and with $v = N - K$.

In the Bransford and Johnson example, for the greatest pairwise difference, the q_{observed} is equal to (cf. Equation 9)

$$q_{\text{observed}} = \frac{M_{1+} - M_{4+}}{\sqrt{MS_{\text{error}} \left(\frac{1}{S} \right)}} \\ = \frac{4.0}{\sqrt{\frac{2.35}{5}}} \\ = 5.83 \quad (10)$$

This value of $q_{\text{observed}} = 5.83$ needs to be compared to a value of q_{critical} for a range of 4 and for $v = N - A = 20 - 4 = 16$ degrees of freedom. From the table of critical values for the Studentized range, we find that $q_{\text{critical}} = 4.05$ for $p = .05$ and 5.19 for $p = .01$; because $q_{\text{observed}} = 5.83$ is larger than $q_{\text{critical}} = 5.59$, we conclude that the "context before" and the "no context" conditions are significantly different at $p < .01$.

If the null hypothesis cannot be rejected for the largest difference, the test stops here. If the null hypothesis is rejected for the largest difference, the two differences with a range of $A - 1$ are examined. If the differences

Figure 2 Structure of Implication of the Pairwise Comparisons When $A = 4$ for the Newman-Keuls Test

Notes: Means are numbered from 1 (the largest) to 4 (the smallest). The pairwise comparisons implied by another one are obtained by following the arrows. When the null hypothesis cannot be rejected for one pairwise comparison, then all of the comparisons included in it are omitted from testing.

are nonsignificant, all other differences contained in that difference are not tested. If the differences are significant, then the procedure is reiterated until all means have been tested or have been declared nonsignificant by implication. This is shown for the Bransford and Johnson example by following the arrows in Figure 2. The results of the Newman-Keuls test are shown in Table 6. Again, we see significant differences between the “context before” condition and all other conditions.

Duncan Test

The Duncan test follows the same general sequential pattern as the Newman-Keuls test. The difference is that the critical values for the test come from a different table. The only difference between the two tests is that the Duncan test uses the Fisher F distribution with a Šidák correction. The Šidák correction is computed using the Šidák inequality

$$\alpha[PC] = 1 - (1 - \alpha[PF])^{\frac{1}{\text{Range} - 1}} \quad (11)$$

where $\alpha[PC]$ is the α -level per comparison and $\alpha[PF]$ is the α -level per family of comparisons. For the Bransford and Johnson example with $A = 4$ conditions,

Table 6 Newman-Keuls Test

	Context Before	Partial Context	Context After	No Context
	$M_{1+} = 7.0$	$M_{2+} = 4.2$	$M_{3+} = 3.2$	$M_{4+} = 3.0$
$M_{1+} = 7.0$		2.8*	3.8**	4.0**
$M_{2+} = 4.2$			1.0	1.2
$M_{3+} = 3.2$				0.2

Notes: Pairwise differences between means for the Bransford and Johnson example. Differences significant at the $p = .05$ level and are indicated by *. Differences significant at the $p = .01$ level and are indicated by **.

Table 7 Duncan Test

	Context Before	Partial Context	Context After	No Context
	$M_{1+} = 7.0$	$M_{2+} = 4.2$	$M_{3+} = 3.2$	$M_{4+} = 3.0$
$M_{1+} = 7.0$		8.3403*	15.3619**	17.0213**
$M_{2+} = 4.2$			1.0638	1.5320
$M_{3+} = 3.2$				0.0425

Notes: F values for the Bransford and Johnson example. Significant F values at the $\alpha[PF] = .05$ level are indicated by *, and at the $\alpha[PF] = .01$ level by **.

$$\begin{aligned} \alpha[PC] &= 1 - (1 - \alpha[PF])^{\frac{1}{\text{Range} - 1}} \\ &= 1 - (1 - .05)^{\frac{1}{3}} \\ &= 0.0170. \end{aligned} \quad (12)$$

The q values computed for the Newman-Keuls test can be changed into F values using the following formula:

$$F_{\text{range}} = \frac{q^2}{2}. \quad (13)$$

For the Bransford and Johnson example, this results in the F values shown in Table 7.

For the first step, the critical F values are 7.10 for an $\alpha[PF]$ of .05 and 12.45 for an $\alpha[PF]$ of .01 with range = $A = 4$ and $v_2 = N - A = 16$ degrees of freedom. Then, the same recursive procedure as the Newman-Keuls test is followed and results in the pattern shown in Table 7.

POSTERIOR DISTRIBUTION

In Bayesian data analysis, a posterior distribution is a probability distribution over hypotheses, possible parameter values, or statistical models, conditional on the observed data. It differs from a prior distribution in that the prior distribution is not conditional on the observed data. The posterior distribution can be a discrete probability distribution or a continuous probability distribution and reflects the credence a rational agent should give to hypotheses, possible parameter values, or statistical models, after observing a set of data. It is one of the applications of the Bayes theorem.

Posterior Distribution Over Hypotheses

A posterior distribution may be used for hypothesis testing when a discrete probability distribution is assigned to two possible outcomes: the hypothesis is true and the hypothesis is false. For example, if the posterior distribution indicates that the probability of a hypothesis being true is 0.80 and that of being false is 0.20, this means that a rational agent believes that the hypothesis being true is 4 times ($0.80/0.20 = 4$) more likely than being false.

Posterior Distribution Over Possible Parameter Values

Another use of the posterior distribution is parameter estimation. It takes the form of a continuous probability distribution over a sample space constituted by all possible values of the parameter of interest. For example, if the parameter of interest is the mean depression score of a population measured in a scale from 0 to 60, the posterior distribution could be a normal distribution where its mean is the most probable value and its standard deviation determines the spread of the distribution. Posterior distributions over possible parameter values are summarized by a credible interval, typically the two values in the 0–60 range within which the central 95% of the probability distribution resides. The two main differences between the credible interval of a posterior distribution and the typical confidence interval are:

1. Unlike confidence intervals, the credible intervals do not just possess the lower bound and the upper bound; they also indicate a probability distribution giving different credence to the values in the range.
2. Only in the credible interval can a rational agent have a 95% confidence that the value of the parameter of interest is within the interval. The traditional confidence interval does not provide this information; rather, the procedure used to calculate the obtained confidence interval produces intervals that contain the actual value of the parameter 95% of the times.

Posterior distributions can be used to estimate any type of parameter such as population mean, population variance, population proportion, difference between two means in a population, population correlation, or population regression coefficient.

Posterior Distribution Over Statistical Models

Posterior distributions over statistical models can be used for model comparison and selection. For example, the comparison between linear regression models (e.g., one with one predictor variable, another one with two predictor variables, and another one with those predictor variables and an interaction). Conceptually, this posterior distribution is equivalent to the one over hypotheses, but in model comparison, the outcome space may contain more than two possible outcomes. In this case, the posterior distribution is a discrete

probability distribution, which assigns a probability to each statistical model. For example, if the posterior distribution assigns a probability of 0.80 to Model 1, 0.10 to Model 2, 0.05 to Model 3, and 0.05 to Model 4, a rational agent must believe that Model 1 is 8 times $(0.80/0.10 = 8)$ more likely than Model 2 and 16 times $(0.80/0.05 = 16)$ more likely than Model 3 and Model 4. It is important to emphasize that the probability of a model is relative to the model it is compared with. A model that is 100 times more likely than the other models in the set may still be a bad model because the competitor models are even worse.

Bayes Theorem

The posterior distribution in Bayesian data analysis is one of the many applications of the Bayes theorem. One form of the Bayes theorem is as follows:

$$P(A|d) = \frac{P(d|A) \times P(A)}{P(d)},$$

which in words can be expressed as:

The letter A is a placeholder for three possible occupants: parameter values (typically represented by the Greek letter θ), hypotheses (represented by H), or models (represented by M). d stands for data, and data are typically summarized with a statistic such as the mean of a variable, the difference between the means of two groups or two conditions, or a proportion or percentage. The meaning of the sign “|” is *conditional on* or *given that*. Therefore, $P(A|d)$ is the probability of A conditional on the observed data or the probability of A given that we observed some data.

Let’s exemplify a posterior distribution with a simple case in the form of hypothesis.

$$P(H|d) = \frac{P(d|H) \times P(H)}{P(d)}.$$

A researcher would like to test a hypothesis H : Person X has an infectious disease. The hypothesis can be either true (denoted by $H+$) or false (denoted by $H-$). This posterior distribution is a discrete probability distribution with two possible outcomes ($H+$ and $H-$); therefore, the sum of the probabilities for each outcome must be 1.

Let’s assume that the prior probability $[P(H)]$ is the probability for any person in a specific city of being infected, and epidemiological information indicates that $P(H+) = 0.08$ and $P(H-) = 0.92$. In this context,

the data are the result in a screening test for that disease, where testing positive is denoted by $d+$ and testing negative by $d-$. The screening test is not perfect and possesses the following characteristics: For people who have the disease, their probability of testing positive in this test (i.e., the likelihood or $P(d+|H+)$ is .95); therefore, the probability of testing negative in this test for those who have the disease $[P(d-|H+)]$ is .05. For those who do not have the disease, the probability of testing positive $[P(d+|H-)]$ is 0.04; therefore, for those people, the probability of testing negative $[P(d-|H-)]$ is 0.96.

The probability of the data or $P(d)$ is the probability of observing the actual data $[P(d+)$ if the observed test is positive, $P(d-)$ if the observed test is negative] regardless of whether people have the disease or not. The probability of the data being positive is calculated by the following expansion:

$$P(d+) = P(d+|H+) \times P(H+) + P(d+|H-) \times P(H-).$$

We can plug in the figures provided earlier:

$$P(d+) = .95 \times 0.08 + 0.04 \times 0.92.$$

$$P(d+) = 0.076 + 0.0368.$$

$$P(d+) \approx 0.1128.$$

Now we have all the elements to obtain the posterior distribution for the case in which a person tested positive in the screening test:

$$P(H+|d+) = \frac{P(d+|H+) \times P(H+)}{P(d+)},$$

$$P(H+|d+) = \frac{.95 \times 0.08}{.1128},$$

$$P(H+|d+) \approx 0.6738.$$

This indicates that if a person tests positive in the screening test, the probability of having the disease $P(H+|d+)$ is 0.6738 or 67.38%. Being a discrete probability distribution, the posterior distribution must add to 1; therefore, the probability of not having the disease for someone who tested positive $P(H-|d+)$ in the screening test is .3262 or 32.62%.

Posterior Odds

A discrete posterior distribution can be summarized with posterior odds: that is the ratio between the probabilities of the posterior distribution that corresponds to two possible outcomes:

$$\text{Posterior odds} = \frac{P(H+ | d+)}{P(H- | d+)}.$$

$$\text{Posterior odds} = \frac{0.6738}{0.3262} \approx 2.0656.$$

The posterior odds can be contrasted with the prior odds, which is the ratio between the probabilities of the same outcomes before observing the data:

$$\text{Prior odds} = \frac{P(H+)}{P(H-)}.$$

$$\text{Prior odds} = \frac{0.08}{0.92} \approx 0.0869.$$

An important component of Bayesian data analysis is the update from the prior distribution to the posterior distribution. In this example, the prior odds for a person to be infected was 0.0869 and the posterior 2.0656. The increase in odds is by a factor of $2.0656/0.0869 \approx 23.75$. This updating factor is also called *Bayes factor* and can also be obtained as the

ratio of the two likelihoods: $\frac{P(d+|H+)}{P(d+|H-)} = \frac{0.95}{0.04} = 23.75$.

POSTMODERNISM

Postmodernism is a mid- to late-20th century philosophical movement that is characterized by deconstruction, disruption, and skepticism. Postmodernism evolved as a reaction to empiricism (the philosophical belief that all knowledge results from experience) and the conservative social and moral principles that

dominated the periods of modernity and modernism. Postmodernism provides a critique of empirical values and challenges the legitimacy of a singular reality. While postmodernist philosophy has extended beyond the humanities to artistic outputs such as the creative arts, architecture, music, and fashion, this entry focuses on the origins of postmodernism, its core principles, and its application within qualitative research.

Origins of Postmodernism

Although postmodernism reached its peak in the second half of the 20th century, a number of late 19th-century philosophers contributed to postmodernist theory. For example, Friedrich Nietzsche (1844–1900) challenged positivist ideals by identifying how an individual's perception impacts their understanding of truth.

The work of Ferdinand de Saussure (1857–1913) also shaped postmodernist theory. Saussure identified that language is made up of spoken or written words (the *signifier*) that served as signs for preexisting or learned conceptualizations (the *signified*) and that it is the *signified* that produces meaning, not the words themselves. Saussure's work highlighted that language use is never passive and later led to the linguistic turn in disciplines such as history during the mid-20th century.

Saussure's work also shaped the foundational precursors to postmodernism—structuralism and poststructuralism. Structuralism is a mid-20th century critical method that was used in disciplines such as anthropology, sociology, and linguistics. It proposed that human activities and culture can be understood by exploring the meaning of structures and patterns found within language. Poststructuralism built upon and critiqued the tenets of structuralism by questioning the notions of stability, power, and neutrality found within structures. Such poststructuralist approaches form the basis of the postmodernism.

Jacques Derrida (1930–2004), Michel Foucault (1926–1984), and Jean-Francois Lyotard (1924–1998) are three of the most notable scholars in postmodernist philosophy. Derrida's seminal work, *Of Grammatology* (1967), focused on the deconstruction of spoken and written signs (words) and noted that the words used by a speaker or author will never be objective even if that was their intention as these words were deliberately chosen to convey a specific message to others. Derrida also posited that the meaning of a word is unstable and changes between individuals, in different contexts, and over time.

Foucault theorized language and discourse were a source of power that can be used to control and modify

human behavior. In works such as *Madness and Civilization: A History of Insanity in the Age of Reason* (1961), *The Birth of the Clinic: An Archaeology of Medical Perception* (1963), *The Order of Things: An Archaeology of the Human Sciences* (1966) and *Discipline and Punish: The Birth of the Prison* (1975), Foucault examined how those in authority are able to subjugate the less powerful through tactics including objectification, surveillance, and normalizing judgment. Foucault postulated that this subjection creates an accepted version of reality through the production of a docile population.

Lyotard is one of the few postmodernist scholars who used the term *postmodern*. Lyotard declared postmodernism to be an “incredulity towards metanarratives” (1984, p. xxiv). Metanarratives, also referred to as *grand narratives*, are generalized stories about a societal group or event that are so common and normalized they are accepted as truth. Postmodernists believe such metanarratives can be used as a control mechanism that can lead to the oppression and marginalization of vulnerable groups and thus must be viewed with skepticism.

Core Principles of Postmodernism

Postmodernism exposes the flaws of modernity by opposing ideologies that are generally accepted as true by society. For example, postmodernists question the modernist ideology that the world is continually advancing in a progressive and linear way. They instead argue that the world is in a constant state of flux and society has not become more humane or sophisticated over time.

Postmodernists also challenge empirical assumptions including causality, totality, and reality. In contesting these assumptions, the postmodernist ruptures the rhetoric of modernist systems of thought by examining the underlying presumptions about the existing *facts* of the phenomenon being explored and how the research itself is being conducted. The core principles of postmodernism are acknowledging the ambiguity and instability of knowledge and the dismissal of a single reality.

Acknowledging the Ambiguity and Instability of Knowledge

Postmodernists reject post-Enlightenment epistemologies by acknowledging knowledge construction, and understanding is dynamic and ambiguous. This ambiguity is in part the result of the evolution of language as the words and discourse that are used to denote a certain concept may not hold the same

meaning over time or context. For example, views on what constitutes acceptable moral behaviors are different between cultures and generations; therefore, applying a contemporary (personal) meaning of morality to information that is collected from another culture or period may lead to misinterpretation and misrepresentation. To decrease this risk of misinterpretation, postmodernists reject the empirical belief that words are neutral vehicles for conveying truth and reality.

The ambiguity of knowledge can also result from imposed systems of control. For example, Foucault and Derrida both claimed archives are a locus of control and authority in social and historical research. This control is exerted by the institution through overt means including determining how and when individuals are able to search for and access materials to gain knowledge and via more covert ways such as deciding which materials will be archived. The latter scenario potentially creates a death of knowledge as materials that are deemed unsuitable by archival staff may be destroyed.

Deconstruction, decentering, and problematizing are three methods used by postmodernists to address the ambiguity and instability of knowledge. Deconstruction is an analytical technique that scrutinizes the nature and context of a phenomenon or system (e.g., a piece of writing, a discipline) by taking apart its construction. With decentering, a key concept or figure is removed from the central focus or position of the analysis, allowing the researcher to probe the origins of and fixed assumptions about the concept or figure. Problematizing is a similar technique to decentering where the researcher isolates and challenges the assumptions and biases that underlie a particular concept, idea, or passage of writing.

Dismissal of a Single Reality

Postmodernists believe reality is a conceptual construct that is influenced by the researcher, their participants, and research data. Because reality is a socially constructed entity, postmodernists adopt a relativist ontology and argue that a nihilism or *lack of reality* about reality exists. That is, it is impossible to show a single truth or reality due to the subjectivity that is involved in privileging one piece of data over another or in the meaning that is applied to it. Consequently, the researcher adopting a postmodernist lens does not strive to represent reality but rather will present only one person's perspective or will bear witness to the unrepresentable aspects of a phenomenon or event.

Bearing witness to the unrepresentable is achieved through the researcher deconstructing what is known or generally accepted about the phenomenon. This deconstruction includes investigating what influence

factors such as underlying ideologies, biases, assumptions, metanarratives, and existing (power) structures may have on contemporary understandings of the studied phenomenon. Engaging in this deconstruction permits a more critical analysis of the phenomenon as the data are contextualized and decentered away from what is already known about the topic.

Application in Qualitative Research

Rather than adopting a positivist lens that values a singular representation of truth or reality, postmodernists accept that there are multiple ways of knowing and plural realities. This acceptance is manifested through the way in which data are collected, analyzed, and disseminated.

A key feature of postmodernism is the disruption of normalized behaviors and traditional practices. Postmodernists may also extend this disruption to data collection by being open to novel ways of searching and locating data. For example, the postmodernist researcher may search online archives for digitized sources or incorporate nontraditional sources (e.g., digitally born sources such as social media outputs, architecture) into their research.

With data analysis, the postmodernist aims to deconstruct, contextualize, and decenter the data. Postmodernists, like poststructuralists, attempt to understand what influence societal structures (e.g., socioeconomic status, politics, gender, race) have on existing knowledge about the subject. Such analysis involves rejecting the universality of *rules* that govern such structures as well as examining and problematizing any prevailing ideologies or metanarratives that relate to the phenomenon or event so that a more inclusive and critical interpretation is developed. During the analysis phase, postmodernists also examine themselves through reflexivity so that they have a deeper self-awareness about the impact such ideologies or sociocultural structures may have on their worldview, and in turn, their interpretation.

The ways in which postmodernists disseminate new knowledge also support multiple ways of knowing. Postmodernists accept there will always be multiple interpretations of the same subject due to the subjective way in which researchers select and interact with data. For example, a postmodernist historical researcher acknowledges that their narrative is at best a tenuous example of *reality* of a past event as it is impossible for them to relive the past, and the sources that were used for the research may be imperfect or incomplete portrayals of the past.

The central role the researcher plays in the research is another area of concern for postmodernists. For

example, postmodernists maintain that the linguistic turn has resulted in greater awareness of how their scholarship can positively or negatively influence a reader's knowledge about the past. Because of such shortfalls, postmodernists typically dismiss the existence of any expert accounts on the subject matter.

POWER

The power of a statistical test is the probability that the selected test will appropriately reject the null hypothesis (i.e., when an alternative hypothesis is true). That is, it refers to the likelihood that the test will not make a Type II error (false negative rate or β). Because power is equal to $1 - \beta$, as Type II error decreases, power increases. Statistical power is influenced by statistical significance, effect size, and sample size. All of these factors are taken into consideration when completing a power analysis.

Primary Factors That Influence Power

Several factors influence power or the ability to detect significant results if they exist: statistical significance, effect size, and sample size. Each of these terms is described in this section.

Statistical Significance

The significance level (α) is the probability of rejecting a null hypothesis that is true. The power of the test ($1 - \beta$) is the probability of correctly rejecting a false null hypothesis. Therefore, as significance levels increase, so does power. One way to increase power is to use a larger significant criterion, which increases the chance of obtaining a statistically significant result (rejecting the null hypothesis). However, doing so increases the risk of obtaining a statistically significant result when the null hypothesis is true (i.e., false positive or Type I error). A commonly used, albeit arbitrary, significance level is $\alpha = .05$, which signifies that there is a 5% probability that a researcher will incorrectly detect a significant effect when one does not actually exist.

Effect Size

Effect size refers to the magnitude of the effect of interest in the population. Larger effects are easier to detect than small effects. Thus, power to detect a significant effect increases as the magnitude of the effect increases. For example, a researcher may be likely to detect a very large difference between two groups but may have more difficulty detecting a small difference. In the latter case involving very small effects, the probability of a Type II error, which refers to not finding a significant difference when one actually exists (i.e., a false negative or β), is high. For instance, if the likelihood of a false negative (β) is .80, and power is equal to $1 - \beta$, then power in this case is .20. So, in general, the power to detect small effects is low, although it can be increased by manipulating other parameters, such as sample size.

Sample Size

Sample size refers to the number of observations (n). In the case of human sciences, this often means the number of people involved in the study. In power analysis, the most frequently asked question is how many observations need to be collected in order to achieve sufficient statistical power. When sample size is large, variation within the sample (standard error) becomes smaller and makes standardized effect size larger. Note that there may be times when recommended sample size (resulting from power analysis) will be inadequate (see example below). Although increasing sample size may increase power, there is recognition that too many observations may lead to mistaken detection of trivial effects that are not clinically significant. By contrast, if too few observations are

used, a hypothesis test will be weak and less convincing. Accordingly, there may be little chance to detect a meaningful effect even when it exists (Type II error).

Power Analysis

Power analysis is typically required by funding agencies and ethics boards because it helps determine the number of observations or participants necessary for recruitment. Power analysis can be done either before (a priori or prospective) or after (post hoc or retrospective) data are collected. A priori power analysis is typically used to determine an appropriate sample size to achieve adequate power and requires determination of the test model that will be used for data analysis (e.g., t -test). Post hoc power analysis is used to determine the magnitude of effect size of the observed sample compared to the population. Generally, a priori power analysis is preferred and done during the design stage of the study.

Although there are no formal standards for power, power of .80 is usually the accepted standard for hypothesis testing.

Calculating Power

Because power is a function of α , n , and effect size, these should be predetermined prior to computing power. Most likely, power calculations are computed in order to predetermine n . For example, a researcher may conduct a power analysis to determine how many people will be needed to detect a significant ($\alpha = .05$) effect with power equal to .80 for a specified statistical test (e.g., analysis of variance). The goal is to achieve a balance of the components that allows the maximum level of power to detect an effect if one exists. In most cases, power is obtained by simple computations or by using power tables.

The following are additional resources for power calculations:

nQuery Advisor —This software is used for sample size estimate and power calculations and contains extensive table entries and many other convenient features.

SamplePower(r) —SamplePower is available from SPSS, an IBM company, and arrives at sample size for a variety of common data analysis situations.

*G*Power*—G*Power allows you to calculate a sample size for a given effect size, alpha level, and power value.

POWER ANALYSIS

Statistical hypothesis tests are used to address research questions of interest in analytical studies (e.g., studies that attempt to establish relationships between variables). Power is the probability of rejecting the null hypothesis of a statistical test when the null hypothesis is false. High power is desirable for a statistical test, as it implies a low false-negative rate. Power analysis involves the calculation of power, or equivalently, the sample size or detectable effect size given specific power, for a study. Power analysis helps evaluate the performance of a study design in repeated experiments. It provides critical information to help select a design prior to the study initiation that ensures the answer to the research question of interest at the end of the study to be not only valid but also efficient and informative. Therefore, power analysis is routinely required in research grant proposals and drug development protocols.

The remainder of this entry is organized into the following five sections: (1) Descriptive Versus Analytical Studies, (2) Statistical Hypothesis Test, (3) Power Analysis and Its Role in Study Design, (4) Factors Affecting Power, and (5) Extended Topics.

Descriptive Versus Analytical Studies

Power analysis is a statistical method used in research study design. However, it is not required for all research study designs. This section briefly reviews the types of research designs in which power analysis is or is not relevant.

Research studies are conducted to either describe characteristics of a population or answer a particular research question (or questions) of interest. Research study design is a framework or the set of methods and procedures used to collect and analyze data on variables specified in the objectives of the research studies.

The type of research design used to meet study objectives is determined by the specific aims of the study and availability of resources. Research studies can be categorized into descriptive and analytical studies.

Descriptive studies, as the name suggests, merely try to describe the data on one or more characteristics of a group of subjects. Generally speaking, these studies do not try to answer questions related to specific hypotheses or establish relationships between variables. Examples of descriptive studies include case reports, case series, and cross-sectional surveys.

In contrast, analytical studies attempt to test a hypothesis and often establish relationships between variables. In typical analytical studies, the researcher assesses the effect of an exposure (or intervention) on an outcome. Analytical studies can be observational (if the exposure is naturally determined) or interventional (if the researcher actively administers the intervention).

Cross-sectional surveys can be either descriptive or analytical studies, depending on whether a question on specific hypothesis is being addressed in the study.

In summary, descriptive studies do not aim to test hypotheses, while analytical studies do. Consequently, power analysis is relevant for the design of analytical studies, but not for descriptive studies. The statistical justification of sample size for descriptive studies that is not based on power analysis is discussed later in this entry.

Statistical Hypothesis Test

A statistical hypothesis test is a method of statistical inference. In the most common cases, there are two, null and alternative, hypotheses. The null hypothesis, often denoted as H_0 , is a hypothesis that is testable on the basis of observed data modeled as the realized values of a collection of random variables. These random variables are assumed to have a joint probability distribution in some set of possible joint distributions. The null hypothesis being tested is exactly that set of possible probability distributions. An alternative hypothesis, often denoted as H_1 , is also proposed for the probability

distribution of the data. The comparison of the two hypotheses (models) is deemed statistically significant if, according to a threshold probability—the significance level, denoted as α —the data are very unlikely to have occurred under the null hypothesis H_0 . A significance-based hypothesis test, the most common form of a hypothesis test, specifies which outcomes of a study may lead to a rejection of the null hypothesis at the prespecified level of significance, while using a prechosen measure of deviation from that hypothesis (the test statistic, or goodness-of-fit measure, often denoted as T). The prechosen level of significance is the maximal allowed *false-positive rate* (or type I error rate). In a significance-based hypothesis test, one can only reject or fail to reject a null hypothesis, rather than “accept a null hypothesis.” The set of outcomes that may lead to a rejection of the null hypothesis is determined based on the distribution of the test statistic under the null hypothesis that does not depend on any unknown parameters.

A common process to conduct a statistical hypothesis test is as follows:

1. Compute the observed value of the test statistic T .
2. Calculate the p value. This is the probability, under the null hypothesis, of sampling a test statistic at least as extreme as the observed statistic (the maximal probability of that event, if the hypothesis is composite). Here, a composite hypothesis refers to a hypothesis that covers a set of values from the parameter space for the joint distribution of the data.
3. Reject the null hypothesis, in favor of the alternative hypothesis, if and only if the p value is less than (or equal to) the significance level α . For most hypothesis tests, the p value needs to be calculated using statistical software, such as SAS, Stata, S-PLUS, R, or SPSS.

Based on this process for conducting a hypothesis test, the components required to perform a test include the following:

1. (in the most common cases) specification of a null (H_0) and an alternative (H_1) hypothesis, the latter of which also determines whether the test is one- or two-sided;
2. a test statistic (T)—as a function of the data—that has a distribution under the null hypothesis that does not depend on unknown parameters;
3. the data;
4. the significance level (α).

A hypothesis test can only be performed after relevant data are collected, often at the end of a study. It

neglects the design of experiment considerations in which power analysis plays an important role.

Power Analysis and Its Role in Study Design

Power is the probability of rejecting the null hypothesis (H_0) of a statistical test when H_0 is false (or the alternative hypothesis H_1 is true). That is,

$$\text{Power} = \Pr(\text{reject } H_0 \mid H_1 \text{ is true}).$$

When H_1 is a specific hypothesis, the aforementioned definition is clear. However, when H_1 is not a hypothesis (or joint probability distribution) with a fixed set of parameters, then power cannot be calculated unless all parameter values are fixed under H_1 . Thus, one generally refers to a test's power against a specific alternative hypothesis.

Power is closely related to the concept of a type II error, which is failure to reject the null hypothesis when the alternative hypothesis is true. It is clear that power equals to $1 - \beta$, where β represents the probability of a type II error, also called the *false-negative rate*. When power increases, the false-negative rate decreases. It is desirable to use a statistical test that is high in power, everything else being equal. A similar concept is the type I error probability, also referred to as the *false-positive rate*, denoted as α in the previous section.

Power analysis is mainly used to justify the minimum sample size required for a study so that one can be reasonably likely to detect an effect of a given size, while saving resources by sparing an unnecessarily excessive sample size. In this sense, power analysis is crucial in evaluating the merit of a study design.

Factors Affecting Power

Parallel to the components required to perform a hypothesis test, the following are the components required to perform a power analysis:

1. a chosen hypothesis test, including whether the test is one- or two-sided;
2. the effect size, which, along with the sample size, determines the distribution of the test statistic under a specific alternative hypothesis;
3. the sample size;
4. the significance level.

Most existing texts designate the last three as the minimal factors affecting power, possibly including whether a test is one- or two-sided as a part of the significance level specification.

Before discussing each specific factor affecting power, let us first assume an *appropriate* hypothesis

test that helps address the primary research question of interest has been chosen.

Significance Level

The most commonly used test significance levels are probabilities of .05, .01, and .001, with .05 being the default choice in most applications, particularly in research grant proposals and new drug approval applications. With a significance level of .05, the probability of the data implying an effect at least as large as the observed effect when the null hypothesis is true must be less than (or equal to) .05, for the null hypothesis of no effect to be rejected. Note that an effect *as large as* the observed effect implies a direction of the effect assessment, with a two- and one-sided test each allowing for an effect to be assessed in both directions and in one specific direction only, respectively.

An easy way to increase the power of a test is to carry out a less conservative test by using a larger significance level, for example, .10 instead of .05. This increases the chance of rejecting the null hypothesis (i.e., obtaining a statistically significant result) when the null hypothesis is false; that is, it reduces the risk of a type II error. However, it also increases the risk of obtaining a statistically significant result (i.e., rejecting the null hypothesis) when the null hypothesis is true; that is, it increases the risk of a type I error. Another scenario where the test significance level may be adjusted is in the presence of multiple testing. For example, when there are k ($k \geq 2$) primary hypotheses being tested, to control the overall type I error rate at the .05 level, each test may be conducted at a $.05/k$ significance level using a Bonferroni adjustment. Note that the conventional significance level of .05 with a two-sided test (or 0.025 with a one-sided test) is in fact an arbitrary choice. There is recent statistical research that suggests an alternative threshold of .005 as a default choice in both hypothesis tests and corresponding power analysis (Johnson, 2013). Such a suggestion, however, has yet to be widely adopted by the practitioners in substance areas.

Effect Size

The magnitude of the effect of interest in the population can be quantified in terms of an effect size, where there is greater power to detect larger effects. While a universal definition of the effect size across all model settings does not exist, effect size is perceived as either a direct value of the quantity of interest or a standardized measure that also accounts for the variability in the population. The notion is, if an effect size is constructed appropriately, along with the sample size, it

completely determines the power with a given significance level.

Precision with which the data are measured is also a quantity often involved in evaluating the effect size. With the same magnitude of the raw effect of interest, the higher precision in the data, the larger the standardized effect size, thus, the larger the power of the test is.

Sample Size

The sample size determines the amount of sampling error inherent in a test result. Other things being equal, effects are harder to detect in smaller samples. Increasing sample size is often the easiest way to boost the statistical power of a test. How increased sample size translates to higher power is a measure of the efficiency of the test—for example, the sample size required for a given power.

Statistical Test

With a given statistical test and significance level, any two components determine the third (among power, effect size, and sample size). The earlier discussion assumes that a hypothesis test is already chosen. However, there may be different choices of a statistical test for the same primary hypothesis of interest or there may be a variety of design considerations that determine the statistical hypothesis test (or statistical model) to be used and, in turn, power of the study. Some related factors are considered in the following paragraphs.

The choice of study end points may affect the power of a study. For example, an appropriate transformation of a continuous end point to better meet model assumptions may result in improved power for evaluating the study objectives. In this case, a parametric test may be more powerful than its nonparametric counterpart. In contrast, categorization (such as dichotomization) of a continuous end point may result in a considerable loss of information in the data, thus a loss of power of the study. However, such a categorization may also be preferable in cases where ease of interpretation of the study results outweighs a moderate loss of power. For example, in smoking cessation studies, a dichotomous outcome of whether one stops smoking is more commonly used than the number of cigarettes smoked (treated as a continuous outcome) as a measure of the smoking cessation outcome, due to both its clinical relevance and ease of interpretation. Even for the same study end points (such as certain categorical outcomes), different tests for the same hypotheses may yield different power in small-to-moderate samples, such as the Pearson's and likelihood ratio chi-squared tests or the Wald score and likelihood ratio tests.

In other scenarios, different study designs may result in different tests being used, which in turn yield different power. For example, other things being equal, a within-subject comparison (using a paired *t*-test) will be considerably more powerful than a between-subject comparison to evaluate an intervention effect. In making a choice between the between- and within-subject comparison-based designs (and a resulting choice of the test), one also needs to make sure it is plausible to assume no change of the expected outcome over time when no intervention is given. This may itself be a strong assumption to make. Similarly, with a fixed total sample size, power is higher for a between-group comparison using a two-sample *t*-test based on equal sample sizes than unequal sample sizes; the more imbalance in the sample size, the lower the power.

The repeated measures design is another example of a commonly used design for evaluating intervention effects by collecting repeated measurements of, say, a continuous primary outcome of interest over time. As a result, tests for the average intervention effects over time become considerably more powerful with the repeated measurements, using either repeated measures analysis of variance or mixed-effects model analysis, than tests for the intervention effects at specific time points using the conventional analysis of variance.

Example

To illustrate some of these factors influencing power, let us consider a research study example in which the main objective is to examine the efficacy of a novel 6-week yoga (YG) intervention given to head and neck cancer patients during their chemoradiation therapy. The outcomes of interest include health-care utilization, as measured by the patient emergency department (ED) visits and feeding tube insertions, and improved patient quality of life as compared to the usual care (UC) group for symptom management.

Study End Point

The primary study end point is ED visit (yes/no) from the first day of chemoradiation therapy until 6 months later. Other end points including the feeding tube insertions (binary) and quality of life (continuous) are all secondary end points. These outcomes are also measured at additional intermediate time points. The primary objective is to compare the ED visit rates between the YG and UC groups by 6 months.

Statistical Test

Based on the primary study objective, a two-sided chi-squared test is considered appropriate for

evaluating the difference in ED visit rate between the two intervention groups by 6 months post baseline.

Significance Level

A conventional 0.05 significance level is used. However, this could be changed, for instance, to 0.025 using a Bonferroni adjustment, if the feeding tube insertion rate was considered a coprimary end point.

Effect Size

Ideally, the target effect size is well defined as a minimal clinically meaningful effect. In reality, however, there is either a lack of consensus on the minimal clinically meaningful effect in the field, implying a range of the effects that experts in the field may consider to be clinically relevant or, more realistically, there is a lack of information on the target effect size, except for estimates from the pilot studies. There was a relevant pilot study that estimated the ED visit rates in the YG and UC groups to be approximately 0.3 and 0.55, respectively, and this was considered a satisfactory effect of the yoga intervention by the study clinicians. Therefore, these estimates were used to compute the effect size for the chi-squared test. When resources permit, a conservative strategy is to select a target effect size smaller than the estimate from the pilot data, due to the high variability of the effect size estimate based on a pilot study with a small sample size.

Sample Size

This study is based on a research grant proposal in which the funding, if received, would allow accrual of a maximum of 200 participants at baseline. Assuming a conservative 25% attrition rate (based on an estimate also from the pilot study), a minimum of 75 patients per group may provide the primary outcome data by 6 months from baseline. While in the final data analysis appropriate techniques will be used to handle the missing data, it is a common practice and considered conservative to base the power analysis on the postattrition sample size.

Power

Based on the aforementioned assumptions, a two-group chi-squared test with a 0.050 two-sided significance level will have 88% power to detect a difference between the YG and UC group ED visit rates of 0.300 and 0.550 (odds ratio of 2.852), respectively, when the sample size in each group is 75. This calculation is done using nQuery 7.0.

Additional software packages for power analysis include PASS and EAST (commercial), and free

packages such as GPower, among others. PROC POWER is a procedure embedded in SAS for power analysis for certain statistical procedures. For more complex study designs, such as adaptive clinical trial designs, one can use simulations to compute power, where specific assumptions for the statistical models used need to be made and justified.

Extended Topics

This section discusses a few extended topics related to power analysis.

Sample Size Justification for Feasibility and Descriptive Studies

The goals of feasibility and descriptive studies are not to test hypotheses but rather to evaluate feasibility, say, of a new intervention; preliminarily assess the intervention effects for hypothesis-generating purposes; or describe characteristics of a population of interest. The corresponding sample size justification may be based on precision of the estimated quantities of interest, such as the feasibility end points of recruitment, intervention adherence, assessment completion, and attrition rates; preliminary intervention effect estimates; or the estimates of the population distribution characteristics of interest, all being potentially useful for planning a larger confirmatory study. The precision may be represented by the width of, say, a 95% confidence interval.

Post Hoc Power Analysis

Post hoc power analysis is generally not advised, as it provides little new information (if not none) beyond the p value itself, and the intention of using post hoc power analysis to *explain* nonsignificant test result is flawed (Hoenig & Heisey, 2001).

Conditional Power

Conditional power is the probability that the final study result will be statistically significant, given the data observed thus far and a specific assumption about the pattern of the data to be observed in the remainder of the study, such as assuming the original design effect, or the effect estimated from the current data, or under the null hypothesis. In many clinical trials, a conditional power calculation at a prespecified point in the study, such as midway, is used as the basis for early termination for futility when there is little evidence of a beneficial treatment effect.

PRAGMATIC STUDY

A pragmatic study focuses on an individual decision maker within an actual real-world situation. The process of undertaking a pragmatic study is first to identify a problem and view it within its broadest context. This leads to research inquiry, which seeks to better understand and ultimately solve the problem. Finally, the research findings often result in policy suggestions, new environmental initiatives, or social change.

Real-World Research

Is it important to debate the philosophy behind our research and the theoretical basis of our research approach? A pragmatic study would be only tangentially interested in such deeper questions, as it puts practical solutions above philosophical discussions. Pragmatic studies often draw upon mixed-methods approaches. Both qualitative and quantitative methods could be employed—whatever methods provide a relevant approach to a given research question. This enables a researcher to develop a holistic analysis to fully incorporate numerous relevant factors into the study. Pragmatic studies are inductive, moving from a complex problem to a general theory of understanding in order to improve a given situation.

Pragmatism is based on understanding human experience. So, pragmatic studies often seek to understand the multiple factors involved in people's actions in a given situation. Thus, pragmatists acknowledge that their inquiry will not lead to certainty because, in theory, nothing in the world is certain. William James, a central figure in this philosophy, noted that a pragmatic study avoids abstract, fixed principles and does not pretend there is only one final truth. Instead, a pragmatic study defines terms by their application to human experience. Most pragmatic researchers are

motivated to conduct research in order to address problems in the real world.

In undertaking pragmatic studies, a researcher believes that the research itself should be used to solve problems and improve human and ecological conditions. Many pragmatists would agree with Gilbert F. White's research goals, which are driven by solving problems that truly affect people and seeking to translate research results into action. This concept exemplifies the basic tenet of a pragmatic study: to conduct research whose results can be translated into practical ends. This often involves policy recommendations or other real-world solutions.

Research Goals

There are four main goals that are often employed to guide pragmatic research: Accept chaos in interrelationships among variables; seek an understanding based on human experience; view a problem as a complex *problematic situation*; and promote activism, democracy, and policy formulation.

First, any given setting provides uncertainty that people define and attempt to resolve; thus, research variables are interdependent. A pragmatic study accepts that any setting is precarious and, indeed, assumes it is a very real feature of every situation, according to pragmatist John Dewey. So, for example, in order to address current ecological problems, which are often an outcome of our attempts to control nature, pragmatism accepts the premise that nature is basically unpredictable. Just as physical scientists question the suitability of linear prediction formulas for weather forecasting, social scientists theorize that interactions between society and the environment assume a nonlinear, chaotic relationship. Pragmatic studies allow for such views by accepting a systems approach to our individual and societal relationships with nature. This provides research flexibility and the ability to select the best possible methods, because pragmatism does not require a linear investigation that seeks one resultant "truth."

A second goal of the pragmatic study is to embrace human experience as the basis for decision making. According to Dewey, experience is what we do, how we learn, and what happens to us. Pragmatist Charles Peirce noted that we should look at general long-term effects and experiences, not just short-term specific ones. Furthermore, knowledge is valued for its usefulness, and understanding of a situation must be gained through one's own experiences or inferred from other people's experiences. Pragmatism focuses on tangible situations, not abstractions. By investigating human

behavior, we actually attempt to understand human experiences. Thus, pragmatic inquiry is only instrumental; it is not an end in itself. The research aim is not to seek an absolute truth, because none exists; rather, it is to formulate policies and aid in improving society. Abstract questions are rarely posed because they are not often directly relevant to a specific research case. So, pragmatic studies investigate human experience to understand the "truth" of what works best in a given situation.

Third, pragmatists seek to improve *problematic situations* rather than test narrow research hypotheses removed from their contexts. Pragmatic studies view a problem not as an isolated event but rather in its full context. A *problematic situation* is investigated through "decision elements" (e.g., social, technological, ecological, economic, perception, and spatial factors) that can be explored concurrently and interactively. There is no fixed progression, and new elements may be discovered to better define the problem. This again points to the use of mixed-methods approaches in pragmatic studies. Qualitative techniques are complementary to quantitative methods and are effective in searching out the complexity of human behavior. A pragmatic researcher seeks to transform a problem by investigating its complex interrelated elements in order to better understand the entire situation. The goal is to present alternatives and to take appropriate action. This leads to social activism and appropriate policies.

Many problems, and thus research questions, are firmly embedded in our society, so the pragmatic aim of transforming a *problematic situation* often confronts the status quo. Pragmatic approaches acknowledge that scholars may need to confront entrenched social and political constraints. This leads to the fourth goal: to contribute a unique perspective that links individual decision making to societal change through public participation. Academic inquiry can inform public choice if research is practical and applied to issues in the real world. A pragmatic study can provide a link to other philosophies through an emphasis on individual decision makers at a grassroots level acting to promote political and social change. A pragmatic study would not stress class, gender, or race differences, but rather seek to encourage each individual to be informed and take part in a truly democratic process. Pragmatists like Dewey believed that our democratic society requires diversity and a complex understanding of the world. Pragmatic behavioral research seeks to understand and reinforce the capacities of individual people for action. Individual and community empowerment can improve a *problematic situation* and eventually lead to social benefits.

Applications

Pragmatism is concerned with understanding and resolving problems that occur in our uncertain world. Thus, environmental topics are particularly conducive to such applied goals, as natural resource management and environmental policy invite practical action. Historically, the work of Gilbert F. White and his students represent one school of thought that focuses on practical research on natural hazards and a broad range of natural resource themes. In addition, pragmatic studies are now also common in many areas of research, including health care and information technology, among others.

Opportunities for Pragmatic Studies

A pragmatic study can address social and environmental perspectives that allow researchers to investigate human experience, human adjustment to various processes, and the subsequent range of choice that individuals and society identify. Pragmatic researchers often speak publicly to raise concerns, inform people, and encourage cooperation. In addition, this approach is particularly valuable at a grassroots level for encouraging ideas and movements regarded as outside the mainstream. For more researchers to employ behavioral pragmatism, it must be recognized as a valid philosophical approach for the social sciences. Most adherents to this approach prefer to spend their time on applied research projects that deal with human problems, rather than partake in debates on philosophical/theoretical concerns. This may explain why pragmatic studies are not well-known in the natural or social sciences. Yet pragmatism allows open and comprehensive investigation, as there are no theoretical constraints that limit the inquiries. Thus, researchers should be aware of and use a pragmatic approach to understanding complex, real-world problems.

PRECISION

The term *precision* refers to how precisely an object of study is measured. Measurements of an object can be made with various degrees of precision. The amount of precision will vary with the research requirements. For example, the measurement of baby ages requires a more precise measurement than that of adult ages; baby ages are measured in months, whereas adult ages are measured in years.

The term *precision* also refers to the degree to which several measurements of the same object show the same or similar results. In this regard, precision is closely related to reliability. The closer the results of measurements, the more precise the object measurement is. Measurement with high precision is very likely to produce the same and predictive results.

This entry focuses on precision with regard to research requirements, accuracy, and reliability.

Research Requirements and Precision

Measurements can be made with various degrees of precision, and how precisely a measurement should be made depends on the research requirement. Precise measurements are always better than imprecise ones, but more precise measurements are not always superior to less precise ones. The description of a residential location as “123 5th Street” is more precise than “inner-city neighborhood.” The description of a historic house built “in March 1876” is much more precise than “in the late 19th century.”

More precise measurements such as “123 5th Street” are not always necessary or desirable. If the description of residential locations such as inner city, inner suburbs, or suburbs satisfies the research requirement, the more precise measurements (i.e., complete residential addresses) necessitate that the researchers identify whether these addresses are located in the inner city, inner suburbs, or suburbs.

An understanding of the degree of precision is also required to direct an efficient data collection. For example, the work experience of people is measured in years or months, but not in hours. The preparation time of students for final exams is measured in hours, but not in minutes or seconds. Any attempt that measures the work experience of people in hours or the student preparation time for final exams in minutes is wasted.

Less precise measurements are not always inferior to more precise ones. In the case of people's work experience, the measurement in years or months is better than hours. Similarly, the measurement of student preparation time for final exams in hours is better than minutes.

Precision and Accuracy

Precision is an important criterion of measurement quality and is often associated with accuracy. In experimental sciences, including social and behavioral sciences, there is low precision, low accuracy; low precision, high accuracy; high precision, low accuracy; and high precision, high accuracy. The measurement with high precision and high accuracy is certainly a perfect measurement that can hardly be made. The best measurement that can be made is to come as close as possible within the limitations of the measuring instruments.

It is easier to be accurate when the measurement does not aim at producing a precise result. In the meantime, if the measurement aims at obtaining a precise result, then it is likely to produce an inaccurate result. The most commonly used illustration to exemplify the difference between precision and accuracy is dart throwing. Dart throwing is neither precise nor accurate when the darts are not clustered together and are not near the center of the target. It is precise but inaccurate when the darts are clustered together but are not near the center of the target. It is accurate but not precise when the darts are not clustered together but their average positions are the center of the target. It is both precise and accurate when the darts are clustered together in the center of the target.

Precision and Reliability

Precision, particularly in the physical sciences, is similar to reliability and is also called reproducibility and consistency. Precise measurements are repeatable and reliable measurements that have similar results. Several conditions are required to produce precise measurements, including proper use of reliable equipment and careful and consistent measurement procedures. In addition, the use of the same instrument from the same manufacturer will likely produce precise measurements, as opposed to switching to another instrument from a different manufacturer.

Precision is also a function of error due to chance variability or random errors. Less precise measurements have more random errors than do more precise ones. Four possible sources of random errors in making

measurements are operator variability, method variability, instrument variability, and subject variability. Operator variability refers to measurement variability due to different operators, such as word choices in an interview or skill in operating a measuring instrument. Method variability refers to the variability in measurement due to use of the wrong measuring procedure. Instrument variability refers to measurement variability due to use of an unreliable instrument, such as an instrument that has not been calibrated recently. Subject variability refers to measurement variability that is due to intrinsic biologic fluctuations, such as fluctuations in mood.

PREDICTIVE DISCRIMINANT ANALYSIS

Predictive discriminant analysis (DA, also called *linear discriminant analysis*) predicts group membership of observations that are described by several quantitative variables and when the group membership of (at least some) the observations is known *a priori*. The variables describing the observations are also called *predictors* or independent variables. DA is closely related to analysis of variance (ANOVA) and multivariate analysis of variance (MANOVA) whose defining equations are formally equivalent to DA). Specifically, ANOVA and MANOVA use a qualitative independent variable (i.e., group membership) to predict one or more quantitative variables, whereas DA uses one or more quantitative

variables (i.e., the predictors) to predict a qualitative dependent variable (group membership).

The Main Idea

With J *a priori* groups, DA linearly combines the predictors to create a set of $(J - 1)$ new orthogonal variables called *discriminant variables* that maximally separate the groups. These discriminant variables best separate the *a priori* groups because an ANOVA performed with the first of these variables will give the largest possible F , whereas the second discriminant variable will give the second largest F (while being orthogonal to the first variable) and so on, up to the last (i.e., $J - 1$) discriminant variable.

Notations

Essential notations are briefly defined here. Scalars are denoted by italic letters, with lower case letter referring to an item and with upper case letters being used to denote the cardinal of a set (e.g., I is the number of observations and i refers to a specific observation). Vectors are denoted by lower case bold letter (e.g., $\mathbf{a}$) and are by default column vectors. Matrices are denoted by upper case bold letter (e.g., $\mathbf{A}$) and in some cases with their number of rows and columns indicated as subscripts (e.g., $\mathbf{X}_{K \times J}$). The transpose operation is indicated by the superscript $\mathbf{T}$ (e.g., $\mathbf{X}^{\mathbf{T}}$ is the transpose of $\mathbf{X}$). The identity matrix is denoted $\mathbf{I}$. The inverse of a matrix is indicated by the superscript -1 (e.g., $\mathbf{X}^{-1}$ is the inverse of $\mathbf{X}$).

Generalized Singular Value Decomposition

The generalized singular value decomposition (GSVD) applies to an I by J rectangular matrix of rank L denoted $\mathbf{X}$. The GSVD decomposes $\mathbf{X}$ under the constraints expressed by two symmetric positive definite matrices (called *constraint matrices* or sometimes *metric matrices*) $\mathbf{M}$ (of dimensions I by I) and $\mathbf{W}$ (of dimensions J by J) into three matrices such that

$$\mathbf{X} = \tilde{\mathbf{U}} \tilde{\Delta} \tilde{\mathbf{V}}^{\mathbf{T}} \quad \text{with} \quad \tilde{\mathbf{V}}^{\mathbf{T}} \mathbf{M} \tilde{\mathbf{V}} = \tilde{\mathbf{U}}^{\mathbf{T}} \mathbf{W} \tilde{\mathbf{U}} = \mathbf{I}_{L \times L} \quad (1)$$

with $\tilde{\Delta}$ being a diagonal matrix of positive numbers called the *singular values* of $\mathbf{X}$ and with $\tilde{\mathbf{U}}$ and $\tilde{\mathbf{V}}$ being called the *left and right singular vectors* of $\mathbf{X}$.

ANOVA for DA

Recall that ANOVA evaluates if the means of a set of groups significantly differ from each other. To make

explicit the relationship between LDA and ANOVA, we show below how ANOVA can be written with notations similar to DA. Take, for example, two groups of five participants each, with the following scores:

$$\begin{aligned} \text{Group 1: } & \begin{bmatrix} 1 & 2 & 5 & 6 & 6 \end{bmatrix}^{\mathbf{T}} \text{ and} \\ \text{Group 2: } & \begin{bmatrix} 8 & 8 & 9 & 11 & 14 \end{bmatrix}^{\mathbf{T}}. \end{aligned} \quad (2)$$

First, organize these scores into one vector denoted $\mathbf{y}$:

$$\mathbf{y} = \begin{bmatrix} 1 & 2 & 5 & 6 & 6 & 8 & 8 & 9 & 11 & 14 \end{bmatrix}^{\mathbf{T}}. \quad (3)$$

The group membership of the observations is stored in a group matrix $\mathbf{X}$. A group matrix has as many rows as there are observations and as many columns as there are groups. In this matrix (containing only 0s and 1s), the element x_{ij} is equal to 1 if the i th observation belongs to Group j and 0 if not. Here we have:

$$\mathbf{X} = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}^{\mathbf{T}}. \quad (4)$$

The number of groups is denoted J (ici $J = 2$), the number of observations *per* group is denoted N (here $N = 2$), and the total number of observations is denoted I (here $I = 10 = 2 \times 5$).

The first step of the analysis computes the mean of all observations called the *grand mean* (also called the *grand barycenter*) as:

$$G = \frac{1}{I} \mathbf{1}^{\mathbf{T}} \mathbf{y} = 7. \quad (5)$$

Next, we compute the vector of group means (also called *group barycenters*) denoted $\mathbf{g}$ and computed as:

$$\begin{aligned} \mathbf{g} &= (\mathbf{X}^{\mathbf{T}} \mathbf{X})^{-1} \mathbf{X}^{\mathbf{T}} \mathbf{y} = \left(\frac{1}{N} \mathbf{I}_{J \times J} \right) \mathbf{X}^{\mathbf{T}} \mathbf{y} = \frac{1}{N} \mathbf{X}^{\mathbf{T}} \mathbf{y} \\ &= \begin{bmatrix} 5 & 0 \\ 0 & 5 \end{bmatrix}^{-1} \times \begin{bmatrix} 20 \\ 50 \end{bmatrix} = \begin{bmatrix} \frac{1}{5} & 0 \\ 0 & \frac{1}{5} \end{bmatrix} \times \begin{bmatrix} 20 \\ 50 \end{bmatrix} \\ &= \begin{bmatrix} 4 \\ 10 \end{bmatrix}. \end{aligned} \quad (6)$$

We then compute three I -dimensional vectors that store the distances (also called *deviations*) at the core of the ANOVA procedure. The first vector—called the *total distance vector*—stores the distance from each observation to the grand mean. Denoted $\mathbf{t}$ (for “total”), it is computed as:

$$\mathbf{t} = \mathbf{y} - \mathbf{1}_{I \times 1} \times G = \begin{bmatrix} 1 \\ 2 \\ 5 \\ 6 \\ 6 \\ 8 \\ 8 \\ 9 \\ 11 \\ 14 \end{bmatrix} - \begin{bmatrix} 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \end{bmatrix} = \begin{bmatrix} -6 \\ -5 \\ -2 \\ -1 \\ -1 \\ 1 \\ 1 \\ 2 \\ 4 \\ 7 \end{bmatrix}. \quad (7)$$

The second vector—called the *within distance vector*—stores the distance from each observation to the mean of its group. Denoted $\mathbf{w}$ (for “within” groups), this vector is computed as:

$$\mathbf{w} = \mathbf{y} - \mathbf{X}\mathbf{g} = \begin{bmatrix} 1 \\ 2 \\ 5 \\ 6 \\ 6 \\ 8 \\ 8 \\ 9 \\ 11 \\ 14 \end{bmatrix} - \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \\ 4 \\ 10 \\ 10 \\ 10 \\ 10 \\ 10 \end{bmatrix} = \begin{bmatrix} -3 \\ -2 \\ 1 \\ 2 \\ 2 \\ -2 \\ -2 \\ -1 \\ 1 \\ 4 \end{bmatrix}. \quad (8)$$

The third vector—called the *between distance vector*—stores for each observation the distance from the mean of its group to the grand mean. Denoted $\mathbf{b}$ (for “between” groups), this vector is computed as:

$$\mathbf{b} = \mathbf{X}\mathbf{g} - \mathbf{1}_{I \times 1} \times G = \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \\ 4 \\ 10 \\ 10 \\ 10 \\ 10 \\ 10 \end{bmatrix} - \begin{bmatrix} 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \\ 7 \end{bmatrix} = \begin{bmatrix} -3 \\ -3 \\ -3 \\ -3 \\ -3 \\ 3 \\ 3 \\ 3 \\ 3 \\ 3 \end{bmatrix}. \quad (9)$$

These three vectors define the fundamental equation of the ANOVA, which indicates that the total distance vector is the sum of the between distance vector and the within distance vector:

$$\mathbf{t} = \mathbf{b} + \mathbf{w} \quad (10)$$

(this equation is obtained by replacing $\mathbf{b}$ and $\mathbf{w}$ by their definition from Equations 9 and 8).

These three distance vectors are then used to compute the corresponding sum of squares. The distances within a group express the experimental error (i.e., what is *not* predicted by the model), when squared and summed, these distances give the sum of squares within groups (denoted SS_{within}) computed as

$$SS_{\text{within}} = \mathbf{w}^T \mathbf{w} = 48. \quad (11)$$

The distances between groups express the experimental effect (i.e., what is *predicted* by the model), when squared and summed, these distances give the sum of squares between groups (denoted SS_{between}) computed as

$$SS_{\text{between}} = \mathbf{b}^T \mathbf{b} = 90. \quad (12)$$

A simple algebraic manipulation shows that the vectors $\mathbf{b}$ and $\mathbf{w}$ are orthogonal to each other (i.e., $\mathbf{w}^T \mathbf{b} = \mathbf{b}^T \mathbf{w} = 0$) and therefore that the total sum of squares is equal to the sum of squares within *plus* the sum of squares between:

$$\mathbf{t}^T \mathbf{t} = \mathbf{w}^T \mathbf{w} + \mathbf{b}^T \mathbf{b} = 90 + 48 = 138 \quad (13)$$

To be comparable in magnitude, these sums of squares are transformed into mean squares by dividing each sum of squares by its number of degrees of freedom. These degrees of freedom correspond to the number of data points that can be chosen and taken into account the constraints in the data. So, for example, the sum of squares between is obtained from J deviations (so here two) but, because, the grand mean is known before computing the deviations. When the first $(J - 1)$ have been chosen, the value of the J th deviation is also automatically known. Therefore, the sum of square between has only $(J - 1)$ degrees of freedom and so, here, we have $df_{\text{between}} = J - 1 = 1$. A similar argument shows that the number of degrees of freedom for SS_{within} is equal to $df_{\text{within}} = I - J = 8$. This way, we obtain the following mean squares:

$$MS_{\text{within}} = \frac{SS_{\text{within}}}{df_{\text{within}}} = \frac{48}{8} = 6 \quad \text{and} \quad (14)$$

$$MS_{\text{between}} = \frac{SS_{\text{between}}}{df_{\text{between}}} = \frac{90}{1} = 90.$$

Finally, the ratio of the mean squares gives the standard F -ratio statistics of the ANOVA:

$$F = \frac{MS_{\text{between}}}{MS_{\text{within}}} = \frac{90}{6} = 15.00. \quad (15)$$

Under the usual statistical hypotheses (e.g., normality of the residuals and homoscedasticity), the F ratio will—when the null hypothesis is true—follow a Fisher distribution with $v_1 = J - 1$ (ici $v_1 = 1$) and $v_2 = N - J$

(ici $v_1 = 8$) degrees of freedom. For this example, the p value associated to an $F = 15.00$ (with $v_1 = 1$ and $v_2 = 8$) is equal to $p = .0047$ —a value small enough to reject the null hypothesis at the usual thresholds.

The formula for F can be rewritten in a way that makes the discriminant analysis optimization problem easier to state. Specifically, F can be rewritten as

$$F = \frac{MS_{\text{between}}}{MS_{\text{within}}} = \frac{SS_{\text{between}}}{SS_{\text{within}}} \times \frac{df_{\text{within}}}{df_{\text{between}}} = \frac{\mathbf{w}^T \mathbf{w}}{\mathbf{b}^T \mathbf{b}} \times \frac{I - J}{J - 1}. \quad (16)$$

This shows that for a specific problem (i.e., number of groups and number of observations being fixed), the F ratio depends only upon the ratio $\frac{\mathbf{w}^T \mathbf{w}}{\mathbf{b}^T \mathbf{b}}$.

Back to DA: Maximization Problem

Recall that DA optimally combines the original predictors to create the discriminant variables that

would give the largest F if used to compute an ANOVA on the groups. This maximization problem—akin to principal component analysis and canonical correlation analysis—can be expressed from Equation 16 by first noting that the term $\frac{I - J}{J - 1}$

plays the role of a constant and can therefore be ignored. So, we are looking for the coefficients of one (or more) linear transformation (which can be stored in a vector $\mathbf{v}$ or in a matrix $\mathbf{V}$ if there are several such linear transformations) of the predictors that will maximize the F ratio from Equation 16. Specifically, if we denote by $\mathbf{Z}$ the matrix of the centered predictors (which could also be normalized or transformed into Z -scores), we are looking for a linear transformation of the columns of $\mathbf{Z}$ that will give a new variable called $\mathbf{h}$ obtained as a linear combination of the columns of $\mathbf{Z}$ with coefficients stored in the vector denoted $\mathbf{z}$ such that $\mathbf{h} = \mathbf{Z}\mathbf{v}$ with the condition that this new variable $\mathbf{h}$ maximizes the F ratio.

There are several equivalent ways of solving the maximization problem of DA, but they all involve the same matrices. Specifically, with K predictors if we denoted (by analogy with the ANOVA) $\mathbf{D}_g$ the $K \times J$ matrix of the between group distances and $\mathbf{C}$ the $J \times J$ within group variance covariance matrix, then the DA maximization problem can be solved in terms of the GSVD as:

$$\mathbf{D}_g = \tilde{\mathbf{U}} \tilde{\mathbf{\Delta}} \tilde{\mathbf{V}}^T \quad \text{with} \quad \tilde{\mathbf{V}}^T (\mathbf{C}^{-1}) \tilde{\mathbf{V}} = \tilde{\mathbf{U}}^T \left(\frac{1}{I} \mathbf{I} \right) \tilde{\mathbf{U}} = \mathbf{I}_{L \times L} \quad (17)$$

where $L \leq \min(K - 1)(J - 1)$ is the rank of $\mathbf{D}_g$. The matrix $\mathbf{H}_g = \tilde{\mathbf{U}} \tilde{\mathbf{\Delta}}$ gives the optimum scores for separating the group means. This decomposition shows that DA finds the best possible separation (i.e., create the largest variance) between the groups means under the constraints imposed by the matrix $\mathbf{C}^{-1}$ (sometimes called the *Mahalanobis distance matrix*, from the eponym Indian statistician). The first generalized singular vectors $\tilde{\mathbf{U}}$ and $\tilde{\mathbf{V}}$ —which are associated to the largest singular value—give the largest F ratios. The following pairs of singular vectors give the subsequent optimal discriminant variables (with the constraint that discriminant variables are pairwise orthogonal). To obtain the values of the discriminant variables for the original observations, the mean of each variable is subtracted from this variable. Denote by $\mathbf{T}$ this centered matrix, then the value of the discriminant variables is obtained by

Figure 1 The Four Variables Measured on the Faces Used in the Example: (1) Between Eye Distance, (2) Length of the Nose, (3) Distance From Eyes to Chin, and (4) Width of the Face

Table 1 Four Variables Measured on the Six Participants (From the Figure in Abdi & Valentin, 2009, p. 159)

ID number	Between-eyes distance	Nose length	Eye-to-chin distance	Width
<i>Females</i>				
F_1	30	26	55	75
F_2	28	26	60	80
F_3	28	26	60	85
<i>Males</i>				
G_1	26	24	60	80
G_2	35	25	61	80
G_3	27	24	57	73

Note: All these measurements are in millimeters and were collected on pictures of size 8cm × 5cm.

multiplying T by the matrix $V = (C^{-1})\tilde{V}$. The whole procedure is illustrated by the following example.

Example: Sex Identification

This small example illustrates DA with a face processing example. Here the task is to identify the sex of a person from measurements performed on a picture of their face. The pictures of six persons (three females and three males, obtained from figure V.6 at page 159 of the 2009 book of Hervé Abdi and Dominique Valentin) were used for the exercise. Four measurements (in millimeters) were collected from these pictures: (1) between-eyes distance, (2) length of the nose, (3) distance from eyes to chin, and (4) width of the face (see Figure 1 for details and Table 1 for the data).

The raw data are stored into the I (here $I = 6$) by K (here $K = 4$) data matrix X :

$$X = \begin{bmatrix} 30 & 26 & 55 & 75 \\ 28 & 26 & 60 & 80 \\ 28 & 26 & 60 & 85 \\ 26 & 24 & 60 & 80 \\ 35 & 25 & 61 & 80 \\ 27 & 24 & 57 & 73 \end{bmatrix}. \quad (18)$$

The number of groups to identify is J (here $J = 2$) as we have a balanced design, the number of observations per group is denoted N (here $N = 4$).

The next step is to create the dependent variable group matrix. This I by J matrix, denoted Y , contains

only 0s and 1s with a value of 1 indicating group membership:

$$Y = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix}^T. \quad (19)$$

(Note, incidentally that, in DA, the roles of X and Y are flipped compared to the ANOVA, cf. Equation 4.)

The K by 1 vector of the grand means for all $K = 4$ variables is denoted g and computed as

$$g = X^T \times \left(\frac{1}{I} \mathbf{1}_{I \times 1} \right) = \begin{bmatrix} 29.00 & 25.17 & 58.83 & 78.83 \end{bmatrix}^T. \quad (20)$$

To eliminate size effects, the matrix is centered to give matrix T (note that in most applications, T would also be normalized or transformed into Z scores):

$$T = X - (\mathbf{1}_I \times \mathbf{1}_K^T) = \begin{bmatrix} 1.00 & 0.83 & -3.83 & -3.83 \\ -1.00 & 0.83 & 1.17 & 1.17 \\ -1.00 & 0.83 & 1.17 & 6.17 \\ -3.00 & -1.17 & 1.17 & 1.17 \\ 6.00 & -0.17 & 2.17 & 1.17 \\ -2.00 & -1.17 & -1.83 & -5.83 \end{bmatrix}. \quad (21)$$

The means of the groups are collected in the $K \times J$ matrix denoted O

$$O = (Y^T Y)^{-1} Y^T X = \begin{bmatrix} 28.67 & 26.00 & 58.33 & 80.00 \\ 29.33 & 24.33 & 59.33 & 77.67 \end{bmatrix}. \quad (22)$$

In matrix $\mathbf{O}$, the intersection of row k and column j stores the value of the mean of the k th group for the j th variable.

The distances of the group means to the grand means of the variables are stored in the $K \times J$ matrix denoted $\mathbf{D}_g$ computed as:

$$\mathbf{D}_g = \mathbf{O} - \left(\mathbf{1}_{K \times 1} \mathbf{g}^T \right) = \begin{bmatrix} -0.33 & 0.83 & -0.50 & 1.17 \\ 0.33 & -0.83 & 0.50 & -1.17 \end{bmatrix}. \quad (23)$$

The value of the distances of the observations to their group means are collected in the I by J matrix $\mathbf{D}_w$ computed as:

$$\mathbf{D}_w = \mathbf{X} - (\mathbf{Y} \times \mathbf{O}) = \begin{bmatrix} 1.33 & 0.00 & -3.33 & -5.00 \\ -0.67 & 0.00 & 1.67 & 0.00 \\ -0.67 & 0.00 & 1.67 & 5.00 \\ -3.3 & -0.33 & 0.67 & 2.33 \\ 5.67 & 0.67 & 1.67 & 2.33 \\ -2.33 & -0.33 & -2.33 & -4.67 \end{bmatrix}. \quad (24)$$

Matrix $\mathbf{D}_w$ is then used to compute the within groups variance/covariance matrix denoted $\mathbf{C}$:

$$\mathbf{C} = \frac{1}{I-K} (\mathbf{D}_w^T \mathbf{D}_w) = \begin{bmatrix} 12.83 & 1.42 & 1.50 & 1.58 \\ 1.42 & 0.17 & 0.42 & 0.58 \\ 1.50 & 0.42 & 6.33 & 10.33 \\ 1.58 & 0.58 & 10.33 & 20.67 \end{bmatrix}, \quad (25)$$

whose inverse is:

$$\mathbf{C}^{-1} = \begin{bmatrix} 304.00 & -2880.00 & 124.00 & -4.00 \\ -2880.00 & 27291.52 & -1175.52 & 38.08 \\ 124.00 & -1175.52 & 51.52 & -2.08 \\ -4.00 & 38.08 & -2.08 & 0.32 \end{bmatrix}. \quad (26)$$

These matrices can now be used to compute the GSVD $\mathbf{D}_g$:

$$\begin{aligned} \mathbf{D}_g &= \tilde{\mathbf{U}} \tilde{\Delta} \tilde{\mathbf{V}}^T \\ &= \begin{bmatrix} -1.73 \\ 1.73 \end{bmatrix} \times \frac{85.05}{\tilde{\Delta}} \\ &\quad \underbrace{\tilde{\mathbf{U}} \text{ with: } \tilde{\mathbf{U}}^T \left(\frac{1}{I} \right) \tilde{\mathbf{U}} = \mathbf{I}}_{\tilde{\mathbf{V}}^T \text{ with: } \tilde{\mathbf{V}}^T (\mathbf{C}^{-1}) \tilde{\mathbf{V}} = \mathbf{I}} \times \begin{bmatrix} 0.0023 & -0.0057 & 0.0034 & -0.0079 \end{bmatrix}. \end{aligned} \quad (27)$$

From this GSVD, the values of the discriminant function for the group means are obtained as:

$$\begin{aligned} \mathbf{H}_g &= \tilde{\mathbf{U}} \tilde{\Delta} \\ &= \mathbf{D}_g (\mathbf{C}^{-1}) \tilde{\mathbf{V}} = \mathbf{D}_g \times \mathbf{V} \\ &= \begin{bmatrix} -147.3094 \\ 147.3094 \end{bmatrix}, \end{aligned} \quad (28)$$

(with $\mathbf{V} = \mathbf{C}^{-1} \tilde{\mathbf{V}}$, note also that matrix $\mathbf{H}_g$ is column centered). Finally, the values of the discriminant function for the original observations are stored in matrix $\mathbf{H}$ computed as (cf. Equation 28):

$$\begin{aligned} \mathbf{H} &= \mathbf{T} (\mathbf{C}^{-1}) \tilde{\mathbf{V}} = \mathbf{T} \times \mathbf{V} \\ &= \begin{bmatrix} -146.64 & -147.06 & -148.23 \\ 148.47 & 147.29 & 146.17 \end{bmatrix}^T. \end{aligned} \quad (29)$$

These factor scores can be used to compute the I by J Euclidean distance matrix between observations and group, which is denoted $\mathbf{D}$ and equal to

$$\hat{\mathbf{D}} = \begin{bmatrix} 0.67 & 0.25 & 0.92 & 295.78 & 294.60 & 293.48 \\ 293.95 & 294.37 & 295.54 & 1.16 & 0.02 & 1.14 \end{bmatrix}^T. \quad (30)$$

Using the distance matrix, the observations are then assigned to the closest group

$$\hat{\mathbf{Y}} = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix}^T. \quad (31)$$

Comparing $\hat{\mathbf{Y}}$ with the group matrix $\mathbf{Y}$ (from Equation 19) shows that prediction is perfect; all six observations are assigned to their groups correctly.

Note, incidentally, that computing a Fisher F using the scores from Equation 29 will result in a maximum value of (see Equation 15):

$$F = \frac{130200.3265}{1} = 130200.3265. \quad (32)$$

This value is larger than any of the original F s.

Evaluating the Model Performance With New Observations

The perfect performance of the discriminant model evaluated previously is a positively biased estimation because the data used to evaluate the model were also the data used to build the model. There are several ways to obtain a less biased (ideally an unbiased) estimate of the performance of the discriminant model. Some parametric approaches exist, but they often rely on assumptions such as multivariate normality that make these approaches undesirable. Contemporary practice therefore prefers to rely on computational cross-validation procedures. Probably the most straightforward of these procedures is to evaluate the model

with *new* data (i.e. data that were, therefore, not used to compute the discriminant function). These new data can be obtained, for example, by sequestering part of the data (i.e., keeping some observations hidden) prior to the analysis and evaluating these observations only *after* the analysis has been performed. Here, for example, we sequestered four observations (two females and two males), stored in a matrix denoted $\mathbf{X}_{\text{sup}}$:

$$\mathbf{X}_{\text{sup}} = \begin{bmatrix} F_1 & 29 & 26 & 58 & 77 \\ F_2 & 30 & 23 & 60 & 83 \\ M_1 & 28 & 25 & 60 & 80 \\ M_2 & 25 & 25 & 50 & 80 \end{bmatrix}. \quad (33)$$

To predict the sex of these observations, we use the parameters estimated from the DA to compute the discriminant function, which will be used, in turn, to assign these observations to the groups. The first step is to preprocess the data matrix in a way that identical to the original data. Here the data were only centered, so we will only center the new data by subtracting the grand mean vector $\mathbf{g}$ from each observation (likewise, if we had normalized the original data, we would normalize the new observations using the normalization parameters used in the original analysis). This gives

$$\begin{aligned} \mathbf{T}_{\text{sup}} &= \mathbf{X}_{\text{sup}} - \begin{pmatrix} \mathbf{1} & \mathbf{g}^T \end{pmatrix}_{I_{\text{sup}} \times I} \\ &= \begin{bmatrix} 0.00 & 0.83 & -0.83 & -1.80 \\ 1.00 & -2.17 & 1.17 & 4.17 \\ -1.00 & -0.17 & 1.17 & 1.17 \\ -4.00 & -0.17 & -8.83 & 1.17 \end{bmatrix}. \end{aligned} \quad (34)$$

The matrix of discriminant scores for these new observations is obtained by replacing $\mathbf{T}$ by $\mathbf{T}_{\text{sup}}$ in Equation 29

$$\begin{aligned} \mathbf{H}_{\text{sup}} &= \mathbf{T}_{\text{sup}} (\mathbf{C}^{-1}) \tilde{\mathbf{V}} = \mathbf{T} \times \mathbf{V} \\ &= \begin{bmatrix} 143.17025 & -382.69389 \\ -18.13598 & 105.38093 \end{bmatrix}^T. \end{aligned} \quad (35)$$

The new observations are now correctly classified only half of the time: a performance much less impressive than with the original DA prediction. When there is no available external datum, a substitute approach could be to predict each observation (or subset of observations) by a model built from all the other observations. This approach, called the *leave one out* (LOO) procedure, is often favored for small samples.

Conclusion

In addition to being mathematically straightforward and easily implemented, DA remains a very popular method for predicting group membership observations described by multiple quantitative variables. It has, however, some limitations that current research is trying to alleviate. A first limitation of DA is to necessitate quantitative predictors; this limitation is addressed by discriminant correspondence analysis that adapts correspondence analysis to handle qualitative variables.

Another problem with DA originates from its assignment rule: An observation is assigned to the closest group, and this gives a 0 or a 1 probability for an observation to belong to a group. This assignment rule seems too strict, as can be illustrated by the example of the prediction of the new faces: a male face with a discriminant score of -18.14 was misclassified as female and a female face was misclassified as male with a discriminant score of -143.17 : The first prediction error feels weaker than the second, but DA gives the same score to both incorrect predictions. *Logistic regression* generalizes DA by providing probabilities of assignment to a class and would preserve the difference between the predictions by assigning different probabilities to them. Note that logistic regression is, however, even more sensitive than DA to the inversion problem discussed below.

Another problem of DA originates from the inversion step of matrix $\mathbf{C}$, because this inversion requires well-conditioned data, it *de facto* precludes using DA with large data sets for which the variables outnumber the observations (a configuration often called the *P >> N problem*). Modern techniques such as ridge can minimize this problem as long as the variables do not *vastly* outnumber the observations. A lot of recent work in artificial intelligence, pattern recognition, and statistics (e.g., deep learning, neural networks, statistical learning, and support vector machines, to cite but a few) is dedicated to develop the next generation of discriminant methods that would overcome the limits of DA while preserving its predictive power.

PREDICTIVE VALIDITY

Predictive validity focuses on the extent to which scores on a measure are related to scores from a criterion measure they administered at a later time. It is a type of *criterion-related validity*. There are two forms of criterion-related validity: predictive validity and concurrent validity. Concurrent-based validity is based on the accuracy of a test's ability to estimate performance on some other measure that could be taken at the same time, while *predictive validity* uses the scores from the new measure to predict performance on a criterion measure that is usually administered at a later time.

Examples of contexts where predictive validity is relevant include the following:

- Scores on a foreign language aptitude measure given at the beginning of an immersion course are used to predict scores on a fluency exam administered at the end of the program.
- Scores on an employment measure administered to new employees at the time of hire are used to predict end-of-quarter job performance ratings from a supervisor.

The primary reason that predictive validity is of interest to users is that a concurrent criterion measure may not be available at the point in time at which decisions must be made. For example, it is not possible to evaluate a student's first-year college success at the time he or she is submitting college applications. Therefore, a measure that is able to correctly identify individuals who are likely to succeed in college at the time of application is a highly desirable tool for admissions counselors.

Before users can make decisions based on scores from a new measure designed to predict future outcomes reliably, they must have evidence that there is a strong relationship between the scores on the measure and the ultimate performance of interest. Such evidence can be obtained through a *predictive validation study*. In such a study, the new measure is administered to a sample of individuals that is representative of the group for whom the measure is intended to be used. Next, researchers must allow enough time to pass for the behavior being predicted to occur. Once it has occurred, an already existing criterion measure is administered to the sample. The strength of the relationship between scores on the new measure and the scores on the criterion measure indicates the degree of predictive validity of the new measure.

The results of a predictive validation study are typically evaluated in one of two ways depending on the level of measurement of the scores from the two measures. In the case when both sets of scores are *continuous*, the degree of predictive validity is established via a *correlation coefficient*, usually the Pearson product-moment correlation coefficient. The correlation coefficient between the two sets of scores is also known as the *validity coefficient*. The validity coefficient can range from -1 to $+1$; large coefficients close to 1 in absolute value indicate high predictive validity of the new measure.

Figure 1 displays hypothetical results of a predictive validation study reflecting a validity coefficient of .93. The predictive validity of the aptitude measure is quite satisfactory because the aptitude measure scores correlate highly with the final exam scores collected at the end of the program; simply put, individuals scoring well on the aptitude measure later score well on the final exam.

In the case when the outcomes on both measures are classifications of individuals, *coefficients of classification agreement* are typically used, which are variations of correlation coefficients for *categorical data*. Evidence of high predictive validity is obtained when the classifications based on the new measure tend to agree with classifications based on the criterion measure.

Figure 1 Scatterplot of Scores on a Foreign Language Aptitude Exam and Language Fluency Exam

Table 1 Cross Classification of Classification From an Employment Measure and Performance Rating

Initial classification from employment measure	End-of-quarter job performance rating from supervisor	
	Unsatisfactory	Satisfactory
Unsatisfactory	14	3
Satisfactory	7	86

Table 1 displays hypothetical data for a predictive validation study reflecting a classification consistency of 91%. The predictive validity of the employment measure is high because the resulting classification aligns well with the supervisor’s job performance rating in almost all cases; simply put, the outcome of the measure predicts well the rating of the supervisor.

When determining the predictive validity of a new measure, the selection of a valid criterion measure is critical. Ideally, as noted by Robert M. Thorndike, criterion measures should be relevant to the desired decisions, free from bias, and reliable. In other words, they should already possess all the ideal measurement conditions that the new measure should also possess. Specifically, criterion measures should be

- *relevant to the desired decisions*—scores or classifications on the criterion measure should closely relate to, or represent, variation on the construct of interest. Previous validation studies and expert opinions should demonstrate the usefulness and appropriateness of the criterion for making inferences and decisions about the construct of interest.

- *free from bias*—scores or classifications on the criterion measure should be free from bias, meaning that they should not be influenced by anything other than the construct of interest. Specifically, scores should not be affected by personal characteristics of the individual, subjective opinions of a rater, or other measurement conditions.
- *reliable*—scores or classifications on the criterion measure should be stable and replicable. That is, conclusions drawn about the construct of interest should not be clouded by inconsistent results across repeated administrations, alternative forms, or a lack of internal consistency of the criterion measure.

If the criterion against which the new measure is compared is invalid because it fails to meet these quality standards, the results of a predictive validation study will be compromised. Put differently, the results from a predictive validation study are only as useful as the quality of the criterion measure that is used in it. It is thus key to select the criterion measure properly to ensure that a lack of a relationship between the scores from the new measure and the scores from the criterion measure is truly due to problems with the new measure and not due to problems with the criterion measure.

Of course, the selection of an appropriate criterion measure will also be influenced by the availability or cost of the measure. Thus, the practical limitations associated with criterion measures that are inconvenient, expensive, or highly impractical to obtain may outweigh other desirable qualities of these measures.

PREDICTOR VARIABLE

Predictor variable is the name given to an independent variable used in regression analyses. The predictor variable provides information on an associated dependent variable regarding a particular outcome. The term

predictor variable arises from an area of applied mathematics that uses probability theory to estimate future occurrences of an event based on collected quantitative evidence.

Predicted outcomes have become part of colloquial phrases in modern language. People speak about having higher risks associated with certain lifestyle choices, or about students' predicted academic performance in a university setting based on scores from standardized assessments. Examples abound in common language regarding predictive variables, yet confusion and fundamental misunderstandings surround the topic. Because of the frequent use and communication of predictor variables in behavioral and medical sciences, it is important for researchers to understand and clearly communicate information related to this topic.

This entry addresses basic assumptions associated with predictor variables and the basic statistical formula used in linear regression. It begins with an explanation of basic concepts and key words commonly associated with predictor variables; following this, basic linear regression formulas are subjected to analysis with an emphasis on predictor variables. The entry concludes with a familiar example of predictor variables used in common applications.

Basic Concepts and Terms

At the most fundamental level, predictor variables are variables that are linked with particular outcomes. As such, predictor variables are extensions of correlational statistics. Therefore, it is important to understand basic correlational concepts. As a function of the correlational relationship, when strength increases, slope, directional trends, and clustering effects become increasingly defined. Slope defines the degree of relationship between variables, with stronger relationships evidencing a steeper slope. The degree of slope varies depending on the relationship of the examined variables. Directional trends are either positive—as the x variable increases, the y variable increases—or negative—as either the x or the y variable increases, the other variable decreases. An example of a positive relationship is height and weight. As people grow, weight typically increases. The relationship is not necessarily a one-to-one ratio, and exceptions certainly exist; however, this relationship is frequently observed. The relationship between weight of clothing worn by people and temperature is an example of a negative relationship between variables. People are unlikely to wear fewer clothing items on days when the weather is below the freezing point, and they are just as unlikely to wear layers of clothing when the temperature nears 100°F. As mentioned in the previous example, variation

will exist in the population—some will choose to wear a light jacket on warm days, whereas others may wear T-shirts and shorts. This variation is called *clustering*. Correlational clusters are the degree to which variables form near each other around an estimate line that provides a representation of a linear trend in the scatterplot. Researchers commonly refer to this linear estimate as the line of best fit. As the observed spread in the cluster decreases, the observed variables exhibit less variance from the line of best fit; this increases the precision of the linear estimate. In a perfect correlational relationship, no deviations from the line of best fit occur, although this is a rare phenomenon.

Traditional correlational and regression models represent the dependent variable—or the variable the researcher is trying to influence—as y . The predictor variable, x , is the item that serves as the independent variable. Once a relationship between a dependent and an independent variable is established, and basic statistical assumptions are met, regression models expand on correlational assumptions. In regression analysis, however, the researcher's primary interest no longer lies in examining the relationship between two or more variables; instead, the researcher's focus turns to predicting a dependent variable (y) based on information obtained about an independent (x) variable. Like the correlational model, information regarding the line of best fit, clustering, direction, and slope is still needed. In regression applications, the line of best fit is called the *regression line*, and the analysis of clustering around the line of best fit becomes a formulaic statistical procedure referred to as the *standard error of estimate*. The standard error of estimate defines the range of error associated with a prediction. For example, for every x variable, the regression line identifies a predicted y score; although a formal prediction is made, there is a range of scores associated with the x score that deviates from the predicted score and leaves the researcher with error in his or her prediction. As an example, imagine a measure that claims to predict an outcome of interest. A score of 10 on this particular test predicts an outcome of 100 on the outcome measure. However, the standard error of estimate in this predictive equation is $x \pm 5$ points. Therefore, the range of error associated with the outcome measure assumes that a subject obtaining a score of 10 on the independent—or predictive—test will likely obtain a score within 95–105 on the outcome measure. This error reveals that although the predictor variable is useful, it (like most predictive equations) remains imperfect.

Another important concept in predictive variables includes the idea of multiple predictor variables. Assuming that the research design and data collection methods meet sample size and other necessary

statistical assumptions, many researchers often prefer to include multiple predictors over one predictor in an attempt to improve the precision and strength of the predictive equation. However, it is important for researchers to recognize that many variables share common variance among them. This simply means that the factors measured in one variable are also measured in another variable, either directly or indirectly, providing a form of statistical redundancy. For example, including height and weight as two predictors may provide an inflated estimate of the predictive accuracy of an equation because, as previously mentioned, when height increases, so does weight. In a situation where weight provides most of a researcher's predictive information, including height might prove useless because it provides another proxy of weight; therefore, it is as if the researcher counted weight twice.

Predictor Variables in a Regression Formula

Statistical textbooks present the standard regression equation in two forms. In secondary education settings, the equation is often expressed as $y = mx + b$. Where y represents the predicted variable, m refers to the slope of the line, x represents the predictor variable, and b is the point at which the regression line intercepts with the Y axis. Although this formula is popular in secondary education textbooks, it is expressed differently among postsecondary-level statistic books, where the formula is written as $\hat{y} = a + bX$. Despite the various representations of this formula, the integral ideas behind it remain intact. The meanings of the symbols in this formula have changed; now, the $\hat{y}$ (read "y-hat") represents the predicted value of y in the previous formula, a in the new equation is the Y intercept, b represents the slope of the regression line, and x remains the dependent variable.

The linear regression equation in its current form allows one predictor variable, yet multiple predictor variables are easily included in regression equations with simple modifications. Using multiple predictors in one equation, researchers are able to use additional information when useful. It is important to note, however, that by using multiple predictive variables, it is not a simple matter of adding the two predictive variables together to create a superior predictive model. When multiple predictive variables are used, they are bound to have some overlap of common variance previously discussed, and researchers or statisticians should remain cognizant of potential errors.

The discussion to this point has centered on predictive equations with linear relationships using continuous predictive variables through simple regression

models. However, other methods of statistical prediction are available. Other methods allow researchers to use dichotomous dependent or independent variables, examine curvilinear relationships, or examine classification error rates. For example, it is possible to use categorical independent variables in linear regression to make predictions of outcomes through procedures such as dummy coding or effect coding. In dummy coding, dichotomous variables are recorded through their occurrence or nonoccurrence. Researchers code variables into zeros or ones to represent the occurrence of an event, where zeros represent the nonoccurrence of an event and ones represent an occurrence. Dummy coding is often used to make predictions regarding categorical variables such as sex, ethnicity, or other demographic information. Similar to dummy coding, effect coding uses ones and zeros with the addition of negative and positive signs added to the one values. Effect coding is often used to differentiate between treatment effects.

When the dependent variable is a categorical metric, methods such as discriminate or logistic regression are more useful. Discriminate regression methods and logistic regression methods are similar in that they allow researchers to measure dichotomous outcome variables (e.g., the occurrence or nonoccurrence of an outcome). Logistic regression methods also allow researchers to determine classification rates of variables of interest to determine the accuracy of a measure. For example, researchers use logistic regression methods to determine correctly and incorrectly identified subjects in order to examine the precision of diagnostic tools.

Practical Example

Now, let us consider an applied example of predictive variables. Imagine that you work for a credit card company. Your company uses a widely known credit rating system to determine the appropriate credit limit and interest rate to assign to a customer. However, you realize that the credit system is based upon general recommendations of the major credit score companies. These scores do not account for your company's specialized customer base, which differs from mainstream customers typically represented in research studies. Interested in improving your company's prediction of creditworthiness, you decide to review your company's records of past clients to determine whether your predictions are similar to or better than those recommended by the credit score companies. In this example, credit scores will serve as predictive or independent variables, and credit outcomes will serve as dependent variables.

Upon accessing your company's records, immediately you realize that there may be a problem with your

research plan. Because your company is small, it cannot absorb high-risk failures; therefore, the company uses the most conservative estimate of creditworthiness based upon three available credit scores. Again, your company does this to avoid high-risk customers who might default on their credit card debt. In your analysis, you are confronted with a major methodological question. Should you continue to use the most conservative estimate and possibly deny potential credit-worthy customers? Perhaps in your company's business model, this approach is the most intuitive; however, this would require three separate statistical analyses resulting in three separate prediction equations. Concerned that the complexity of this approach might cause more selection errors in application due to employees using the wrong statistical formula, you choose instead to use a statistical analysis method that will yield one formula for your company's employees to use.

Next, you consider your formulaic method, as always with the intent to provide the best predictive equation. You are considering using one of the following three approaches: a weight of the three scores in one formal equation, an average of the three credit-ranking scores, or three separate analyses of the three credit-ranking scores to determine which company provides the most precise information about your customer base. If you use a weighted approach that includes all three scores, your analysis will provide an inflated predictive estimate. Said differently, your predictive equation will look as if it is stronger than it actually is. This is because these three credit-ranking scores measure many of the same customer characteristics that the other credit-score companies measure (e.g., the frequency that customers pay their bills on time, the amount of debt they have, if they have previously defaulted on other debts). These overlapping measures provide statistical redundancies. Realizing that you wish to avoid unnecessary error, you decide that the amount of shared variance among the three scores is too high and will likely provide false confidence in your analysis.

You then consider using an arithmetic average of the three credit score rankings. However, because of the sometimes large variability among credit rating scores, as well as incomplete information, you determine that averaging the three scores may result in a less precise measure of a credit ranking. Therefore, you consider analyzing the three credit scores individually and using the scores from the credit-ranking company that provides the strongest predictive equation. This approach is perhaps the most intuitive. Your analysis will reveal the most precise information for your customer base while reducing unnecessary fees from redundant and

less precise information provided by other companies. Additionally, because only one score is presented to your customer service employees—from which they will make their decisions—fewer errors in the approval process are likely.

PRE-EXPERIMENTAL DESIGNS

In pre-experimental designs, either a single group of participants or multiple groups are observed after some intervention or treatment presumed to cause change. Although they do follow some basic steps used in experiments, pre-experimental designs either fail to include a pretest, a control or comparison group, or both; in addition, no randomization procedures are used to control for extraneous variables. Thus, they are considered “pre-,” indicating they are preparatory or prerequisite to true experimental designs. Pre-experimental designs represent the simplest form of research designs. Together with quasi-experimental designs and true experimental (also called randomized experimental) designs, they make the three basic categories of designs with an intervention. Each contains subdesigns with specific strengths and weaknesses.

Because the validity of pre-experimental designs is threatened by inadequate control during implementation, it is difficult or impossible to rule out rival hypotheses or explanations. Therefore, researchers should be especially cautious when interpreting and generalizing the results from pre-experimental studies. However, pre-experimental designs are cost-effective ways to explore whether a potential intervention merits further investigation. They might be particularly useful when

there are less than perfect conditions for true experimental designs. These may include the restraints of time, space, participants, resources, and ethical issues; logistical constraints, such as the investigation of a small atypical sample; or the evaluation of a previous intervention without adequate planning of the research design. Under those circumstances, as long as appropriate caution is taken while making interpretations and generalizations, results from pre-experimental designs could still be suggestive to the field and future research.

This entry first describes the notations used to diagram pre-experimental designs. Next, this entry discusses the major types of pre-experimental designs and possible improvements to these designs. The entry concludes with a brief presentation of the limitations and benefits of pre-experimental designs.

Diagramming Pre-Experimental Designs

Some useful designations are widely used to clarify the different designs. NR indicates that the assignment of participants into groups is nonrandom. E represents the group of participants exposed to the experimental variable or event (usually an intervention or treatment), whereas C represents the control or comparison group. The intervention or treatment is expressed as X, the effects of which are to be measured, whereas ~X either means no intervention or the usual treatment. Thus, X and ~X signify two different levels of the independent variable in a study. O refers to the observation or measurement of the dependent variable. This can be done by observing behaviors, conducting interviews, administering tests, and so on. The X (or ~X) and Os in a given row are applied to the same group of participants, either E or C. The left-to-right dimension reflects the temporal order.

Types of Pre-Experimental Designs

Three major types of pre-experimental designs are commonly used, either because the research preplanning is inadequate, causing unanticipated problems, or perhaps the situation makes a pretest or a comparison group impossible.

One-Group Posttest-Only Design

The first pre-experimental design, the one-group posttest-only design, is also called the one-shot case study or case study design. In this subdesign, all the participants are assigned nonrandomly into the intervention group. Then, this whole group of participants is presented with some kind of intervention, such as a new curriculum, a new drug, or a new service. After

that, the outcome performance is measured as the only posttest. The design is shown as follows:

Group	Intervention	Posttest
E:	X	O

Although the goal of this design is to justify the effect of the intervention on the outcome, it is impossible without a pretest to know whether any change has occurred to this group. It is also impossible to determine whether the intervention has made a difference compared to the situation where no intervention has been implemented because there is no comparison group. Thus, such a design does not satisfy even the minimum condition for a research problem to investigate a relationship or comparison. Therefore, it does not merit the title of experiment.

Obviously, the validity of this design is seriously threatened in many ways. First, the participants are not randomly selected, so external validity could not be determined. Second, the participants are not randomly assigned into experimental and comparison groups, and no steps are taken to ensure that the intervention was the only thing going on during the process. Historical events or maturation may also have an influence on the posttest results. But nothing else is measured to determine what extraneous factors may have been confounded with the intervention. Thus, internal validity is threatened.

With only the posttest scores in hand, this one-group posttest-only design merely provides a reference point. If other specific background information is available, such as the results from an earlier group, an earlier time point, or the general population, the results may indicate the intervention's effect to some extent and be suggestive for future study.

One-Group Pretest-Posttest Design

The second pre-experimental design is the one-group pretest-posttest design. In this approach, all the participants are first assigned to the experimental group. Then, the group is observed at two time points. One observation in the form of a pretest is recorded before the intervention (independent variable). And then after the intervention, a second observation is conducted in the form of a posttest. Changes from the pretest to the posttest are the outcomes of interest, which are presumed to be the result of the intervention. However, there is no comparison group. The design could be shown as follows:

E:	O ₁	X	O ₂
----	----------------	---	----------------

This pre-experimental design is superior to the previous one in that it has included a pretest to determine

the baseline score. This makes it possible to compare the group's performance before and after the intervention. So now, researchers at least know whether a change in the outcome or dependent variable has taken place within the same group. But without a comparison group, it is still impossible to clarify whether this change would happen even without the application of the intervention—that is, whether any change from the pretest to the posttest is due to the intervention only and not due to other extraneous variables.

Several categories of uncontrolled extraneous variables could lead to alternative explanations of any differences between the pretest and the posttest, confusing the possible effects of the intervention.

The first extraneous variable is related to history. That is, during the time span between the pretest and the posttest, many other events may have occurred in addition to the intervention. Thus, the results could be attributed to these as well as to the intervention. In the second place, maturation changes in the participants could also produce differences between the pretest and the posttest scores. As people get older, they may become better at the outcome variable at the same time as the intervention occurs. Similarly, carryover effects are also a possible problem in this design because taking the pretest could influence the posttest. Participants may have learned from the pretest and perform better at the posttest if the two measurements are the same or overlap a lot. Their performance may also vary because of the difference in either the instruments or the implementation processes between the two. Finally, if the experimental group is selected because of extreme scores on some type of instrument, such as the very best or the very worst on a test, then the differences between the pretest and the posttest scores could be due to statistical regression toward the mean. There is a tendency for extreme scorers to move toward the average or more typical performance on subsequent tests.

Any of these above factors may cast threats on the validity of this design. The failure to rule out plausible alternative explanations makes it very difficult to generalize with any kind of confidence about any causal relation between the intervention and the observed change.

However, the one-group pretest–posttest design still allows ruling out some alternative hypotheses by including both pretest and posttest and offering suggestive implications for future study.

Posttest-Only Nonequivalent Groups Design

The third pre-experimental design is the posttest-only nonequivalent groups design, which is also called static-group comparison or cross-sectional study. In this subdesign, participants are assigned into two

groups for comparison. However, the experimental and comparison groups again are determined nonrandomly. After that, the experimental group receives the treatment and the comparison group does not. The subsequent difference between the two groups, which is assumed to reflect the influence of the treatment, is measured by the posttest. This design could be thought of as adding a comparison group to the one-group posttest-only design. It could be diagrammed as follows:

NR E: X O

NR C: ~X O

This design attempts to make a comparison by including a group that does not receive the treatment. However, without randomization and a pretest, it is difficult to know whether there is any pre-existing difference between the two groups. The nonequivalent group is picked up for the purpose of comparison, but its comparability is questionable. Any differences between the two groups before the treatment could become rival explanations for the difference at posttest. It would be difficult to make a conclusion about the effects of the treatment because of unknown differences between the groups. Ideally, with a comparison group, one could be more confident about the intervention's effect if the two groups do go through everything in the same way from the same environment, except for the treatment. However, without any assurance about the equality of the two groups, extraneous factors such as history, maturation, attrition, and statistical regression may affect the two groups differently and contaminate the result at the posttest. An example of history could be that participants in the comparison group seek improvement from some other programs or, on the other hand, become discouraged by the design. Also, if the two groups are nonequivalent at the beginning, the maturation process might be very different across the same time span. If more participants in the experimental group drop out from the treatment, or more participants in the comparison group drop out because they do not feel that they have gained any benefits, such unequal attrition could become a serious threat to the validity of the design. As for statistical regression, it could always be a threat if one or both of the groups were selected from an extreme population.

This pre-experimental design offers us more information and confidence than the one-group pretest-only or the one-group pretest–posttest design by including a comparison group, as long as the above problems related to nonrandom assignment and lack of pretests are well considered when making explanations and implications.

Improvements to Pre-Experimental Designs

One-Group Posttest-Only Design

By following Donald Campbell's reasoning about pattern matching, the one-group posttest-only design could be improved in interpretability. Such improvement is achieved through adding multiple, unique, and substantive posttests to the original design. It could be expressed as follows:

$$E: X \quad O_{1A} \quad O_{1B} \quad \cdots \quad O_{1N}$$

Here, the posttests (O_{1A} , O_{1B} $\cdots$ O_{1N}) represent measurements of different constructs after the intervention. Theoretically, when the possible causes are known, the pattern of effects could be matched by the results from the measurements. Suppose a specific and observable pattern of results is predicted by the implementation of an intervention. The researcher could conduct multiple posttests to collect data about each of the results so that the effects of the intervention could be either supported or disputed. Such collection of convergent evidence is different from the previous design, in which only one posttest construct is assessed.

However, the pattern-matching logic is most compelling when the effects are known and the causes are to be discovered retrospectively, such as the detection of a series of clues left by a criminal. But the pre-experimental designs work just the opposite way. In a prospective study, the causes are predetermined and the effects are unknown. To decrease the possibility of Type I errors, which are very likely considering the human tendency to spot patterns even in random data, well-reasoned specification of a unique pattern beforehand is required to support the presumed relation between intervention and its effects.

One-Group Pretest–Posttest Design

Some variations could also be made to improve the interpretability of the one-group pretest–posttest design. The threats from maturation and regression could be reduced by simply adding a second pretest prior to the first pretest, which could be represented as follows:

$$E: O_1 \quad O_2 \quad X \quad O_3$$

Preferably, the time between O_1 and O_2 equals the time between O_2 and O_3 . With two pretests, the potential biases that might exist in the difference between the second pretest and the posttest, such as the natural improvement in performance as the participants mature or the tendency to regress to the average level, could be clarified by investigating the difference between the two pretests. If the difference between O_2 and O_3 is

much greater than the difference between O_1 and O_2 , one could be pretty confident in stating that the intervention (X) has made a difference. However, in cases where the trend of maturation is nonlinear, more pretests before the intervention would be needed to capture that.

Similar to the improvement to the one-group posttest-only design discussed earlier, adding another unique and substantive dependent variable to the original one-group pretest–posttest design could also help reduce potential threats. This could be diagrammed as follows:

$$E: O_{1A} \quad O_{1B} \quad X \quad O_{2A} \quad O_{2B}$$

Here, in addition to Measure A, which is assessed during both pretest and posttest, a nonequivalent Measure B is also assessed at the same two time points to the same experimental group. If Measure A is hypothesized to change with the implementation of the intervention and Measure B is expected to remain the same, both of the measures would face the validity threats in the same way. With such divergent evidence between two mutually exclusive dependent variables, one could be much more confident about the effects of the intervention because both of the dependent variables are exposed to the same set of environment causes to the same degree.

Another improvement could be made by converting the design into a time series design as follows:

$$E: O_1 \quad O_2 \quad O_3 \quad O_4 \quad X \quad O_5 \quad O_6 \quad O_7 \quad O_8$$

In such a design, several earlier observations (Pretests 1, 2, and 3) and several later observations (Posttests 6, 7, and 8) are added. Suppose there was little change observed between Pretest 1, Pretest 2, and Pretest 3 prior to the intervention, but observable changes occurred after the intervention in the posttest, it would be pretty convincing to state that the intervention or treatment has altered the trend of target development. The key point here is to have multiple (at least three) pretests to establish a baseline.

Posttest-Only Nonequivalent Groups Design

Because the major weakness of the posttest-only nonequivalent groups design is the nonequivalence of the two groups, one possible improvement is to have a pretest on the dependent variable for both groups. Then the design changes to a better, but still weak, pretest–posttest nonequivalent comparison group design. Even if the groups were equivalent on the dependent variable at the pretest, they may still differ on other variables such as demographics. Therefore, other statistical attempts could be applied to check

whether the groups differ on demographic or other available information. If no statistically significant differences could be found on gender, ethnicity, social class, and so on between the two groups, one would be more confident to consider them similar. However, “not significantly different” does not ensure equivalence, and one can never measure all of the possible crucial participant characteristics in actual research.

Sometimes, it is impractical or even unethical to have a comparison group that does not receive the treatment. Under such circumstances, a wait-list comparison group design is often recommended. Here, all participants would receive the treatment eventually, but some are assigned, preferably randomly, to a waiting list that would receive the treatment later than the group with immediate intervention. Both groups are assessed when they first enter the study. The immediate intervention group would receive the treatment then, and the wait-list group would not. After that, a second assessment is conducted on both groups. Then it is the wait-list group’s turn to receive the same treatment as the immediate intervention group received. This group would be assessed again after the treatment. The diagram of the wait-list comparison group design could be shown as follows:

Although such design gives all the participants opportunity for treatment, it is only practical when the intervention is relatively brief, a few months at most, and when it is ethical and practical to have the wait-list group wait for its treatment.

Limitations and Benefits

Pre-experimental designs do not have random assignment of participants and are missing a comparison group, a pretest, or both. Therefore, they provide very little support for the effectiveness of the intervention or treatment, but they are useful and flexible when limited resources or ethical issues make well-controlled experiments impossible. In spite of their limitations, pre-experimental designs could offer some basic descriptive information for further research.

PRETEST SENSITIZATION

Pretest sensitization refers to the potential or actuality of a pretreatment assessment’s effect on subjects in an experiment. The term has different meanings in various disciplines. In medicine and biology, it typically refers to a physical reaction to an initial administration of a drug or regimen. In the social sciences, it has come to mean a cognitive or psychological change in a subject due to administration of a test or observation of the subject. Although the mechanism of sensitization is typically not investigated or even known, the effect on behavior or response has been long documented. This is referred to here as the *pretest effect*. This entry focuses on the research of this phenomenon, methods of evaluation, and related statistical considerations.

Research

Pretest effects have been of concern for many decades. Glenn H. Bracht and Gene V. Glass discussed pretest effects in the context of external validity problems in interpreting research. That is, if a pretest is given in the

context of the experiment, but will not normally be employed in practice, what is the potential effect of the pretest on the outcomes, because in effect it has become part of the treatment? Few authors have followed up this line of critical analysis of research in the intervening years, so this external validity problem is probably understudied and underreported.

Victor L. Willson and Richard R. Putnam conducted a meta-analysis of randomized experiments that directly examined the effects of giving a pretest versus not giving one for various kinds of tests, including cognitive, psychological, and even behavioral/physical measurements. They discussed the classic Solomon four-group design as the original method intended to evaluate the effects of a pretest on posttest performance. In this design, four groups are randomized into treatment or control, and within each subgroup, a pretest was given and withheld. Analysis of variance provides results for the effect of the pretest as well as of pretest-treatment interaction. The latter is particularly of interest if it is significant. Depending on the direction of the effect, its presence will indicate the nature of the pretest effect, either enhancing or suppressing the treatment effect in comparison with control conditions. Willson and Putnam reported that pretest effects on cognitive and psychological functioning were positive, enhancing both on posttest scores in comparison to non-pretested groups. Cognitive measurements evoked greater effects than personality or psychological measurements or reports of behavior, but all can substantially alter the interpretation of experimental results if not considered. Their conclusion was that such effects typically peak at about 2 weeks, and after a month or so diminish to a fraction of a standard deviation, perhaps 0.10–0.20 over longer periods. These values are consistent with the reports of the Educational Testing Service for its various tests for test-takers who retake a test after a year. The mechanism for this was not discussed, and in the intervening 25 years, little research has focused on the actual cognitive processes that increase performance. Indirect evidence, however, from well-established research on memory, activation theory, or other cognitive theory such as dual coding can provide rationales for such effects.

Donna T. Heinsman and William R. Shadish examined the effect of pretests on randomized and nonrandomized studies using meta-analysis as part of a broader study of the differences in the two types of designs. They found that greater pretest differences between experimental and control groups were associated with greater differences in outcomes between randomized and nonrandomized designs, with nonrandomized designs producing results too great in comparison. This suggests that simply adjusting the effect statistically using

analysis of covariance will not produce good estimates of treatments in nonrandomized designs.

Pretest effects have been found in many contexts. David A. Kravitz and William K. Balzer argued for such effects in nonrandomized experimental studies on performance appraisal used in business. Shadish, G. E. Matt, A. M. Navarro, and G. Phillips reported pretest biases in nonrandomized treatment groups in psychotherapy studies. In an experimental study of pretest format effects as mediators of the relationship between beliefs about tests and test performance, D. Chan, N. Schmitt, J. M. Sacco, and R. P. DeShon conducted an experiment in which all participants were provided example items of the type of test they were to take (both cognitive and psychological) with ratings of the face validity, fairness, and applicability given prior to administration of the actual tests. The structural equation model they analyzed supported a complete mediation model of the effect of beliefs about tests on posttest performance by pretest ratings of the sample items. This indicates that pretest effects can depend on the initial knowledge or belief structure about the type of testing involved. This also suggests that the work by researchers such as Carol S. Dweck and colleagues on academic self-concept and motivation indicated that they may play an important role in pretest effects, but this has not been investigated or established.

Proposed Methods to Account for Pretest Sensitization

Although the Solomon four-group design was proposed as a standard method to evaluate pretest sensitization, James H. Bray, Scott E. Maxwell, and George S. Howard argued that such designs or even analysis of covariance designs with pretest as covariate failed to properly account for the sensitization that could occur in self-report studies. They proposed that subjects report *ex post facto* their pretest condition and that researchers use that as a covariate or as a basis for examining treatment differences. Mirjam Sprangers and Johan Hoogstraten evaluated the effect of retrospective construction of pretests by subjects on communication skills. They concluded that treatments may interfere with subjects' report of their pretreatment condition compared to control subjects, which they discuss as response shift, an internal change in subjects' standards or orientation. Clara C. Pratt, William M. McGuigan, and Aphra R. Katzev found just the opposite, that retrospective pretests prevented response shifts. Response shift analysis is discussed later as a variant on pretest sensitization.

Tony C. Lam and Priscilla Bengo compared three retrospective methods of measuring elementary grade

school teachers' self-reported change in mathematics instructional practices: the posttest with retrospective pretest method (reporting current practices and earlier practices), the posttest with perceived change method (reporting current practice and the amount and direction of change), and perceived change method (reporting only the amount and direction of change). Teachers in the posttest with retrospective pretest condition reported the least amount of change, followed by teachers in the posttest with perceived change condition, whereas teachers in the perceived change condition reported the greatest amount of change. Their explanation for the findings focused on differential satisficing (responding with minimally adequate rather than optimal effort) of teachers caused by differences in cognitive demands among the three methods. Greater task difficulty leads to greater satisficing, which causes respondents to resort more to socially desirable responses. This study has not yet been replicated, however.

Whether to assess retrospective pretests or not remains inconclusive, perhaps dependent on the nature of the assessment. Subjects are known to be more or less reliable in self-assessments, depending on the type of assessment. The literature on self-report is voluminous and much too large to summarize here. One example, however, is that children and adolescents are more reliable reporting internalizing problems (and provide better validity evidence than other observers) compared to their self-reports of externalizing problems, and these responses remain reliable across time. Reconstructive memory may play a greater role in experiential retrospective pretests than stable trait assessment, however. The Lam and Bengo result may, in fact, support such reconstruction as much as cognitive demand. This remains an area to investigate.

Statistical Considerations

Although randomization into treatments as recommended in the Solomon four-group design is desirable, it does not completely account for potential pretest sensitization. The interaction effect of treatment by pretest condition provides an average effect across pretest values, but it does not evaluate differential effects across pretest values. That is, treatment effect differences might vary linearly (or nonlinearly) from low pretest scores to high pretest scores. P. Dugard and J. Todman commented that some researchers simply examine gain scores from pretests, and they argued that this method will produce statistical problems. Functionally, a gain score is simply a regression in which the regression weight is 1.0 rather than the ordinary *b*-weight from least-squares regression. Obviously, such an estimate is potentially biased and inefficient. The

best way to examine these effects is to construct within the pretested groups a pretest-treatment interaction variable. Patricia Cohen, Jacob Cohen, Stephen G. West, and Leona S. Aiken discussed constructing interval-category interaction variables by centering the interval variable, constructing a contrast for the treatment variable, and multiplying the two together to produce a new variable that can be included in an analysis of covariance. Because the pretest is available for only half the Solomon design (at least for a balanced, equal sample size per group design), power is reduced, so if one is contemplating this analysis, appropriate adjustments to the sample size of the pretested groups is in order. The design can be modified so that it is proportional, but with a larger sample size in the pretested groups than the unpretested groups. That, in turn, may increase study costs if collecting the pretest data has significant costs associated with it. Still, this approach will permit a more refined examination of the pretest effects on individuals.

Expanding the covariate approach mentioned above, several additional design considerations should be evaluated. First, pretest effects may be nonlinear, such as a quadratic effect that either levels off for high pretest values (possibly because of ceiling effects of the test) or increases and then decreases with pretest values as treatment becomes less effective for either low or high pretest values. Relatedly, a control group may have a linear relationship with the pretest values whereas the treatment exhibits a quadratic effect. These effects can be modeled.

Yet more elaborate modeling may be important in observational studies using path analysis or structural equation modeling (SEM). Chan et al. used SEM to examine pretesting as a mediator between beliefs and test performance, for example. Pretest score is often included in SEM models as an exogenous predictor. Less frequently, pretest-covariate interaction variables are considered and evaluated, although the potential for their existence and explanatory unpacking of findings is great.

Another approach to pretest sensitization in design of studies is by conducting multiple measurements over time, if it is appropriate. With growth modeling or even time-series modeling of such data, both individuals' and groups' data can be examined for differential intercepts and slopes across the measurements. In this case, the pretest score is ignored as a measurement in the growth or time series design, but pretested and nonpretested groups are analyzed separately, perhaps first as a multiple-group growth or time series model constrained for all parameters equal, then as unconstrained separate models with parameters released as indicated by tests such as chi-square modification indexes in SEM. Of course, such models can be constructed even

for single time-point measurement after pretesting, but the capability to examine cross-time differences might provide greater understanding of the pretest effects. Response shifts for internal standards may be examined as a change in intercept between any one time point and the successor; the difficulty is determining when the shift occurred. Using an information measure such as the Akaike information criterion may be helpful in that situation.

Future Research

Pretest sensitization exists as a predictable effect in social science research design, varying in its strength dependent on the nature of the measurement of the pretest. Although the effect appears to wax and wane over a period of weeks and months, it can produce a long-term albeit small change upward in means of groups receiving pretests. Retrospective reporting provides an alternative that has potential to reduce or remove the pretest effect, but much research remains to determine its salience with respect to type of pretest, length of time required to construct the retrospective estimate, and form of the measurement.

PRETEST–POSTTEST DESIGN

The basic premise behind the pretest–posttest design involves obtaining a pretest measure of the outcome of interest prior to administering some treatment, followed by a posttest on the same measure after treatment occurs. If a change has occurred, then that is consistent with a hypothesis that the intervention caused the change. Pretest–posttest designs are employed in both experimental and quasi-experimental research and can be used with or without control groups. For example, quasi-experimental pretest–posttest designs may or may not include control groups, whereas experimental pretest–posttest designs must include control groups. Furthermore, despite the versatility of the pretest–posttest designs, in general, they still have limitations, including threats to internal validity. Although such threats are of particular concern for quasi-experimental pretest–posttest designs, experimental pretest–posttest designs also contain threats to internal validity.

Types of Pretest–Posttest Designs Without Control Groups

One-Group Pretest–Posttest Design

In the simplest pretest–posttest design, researchers gather data about some outcome through a single pretest, administer a treatment, and then gather posttest data on the same measure. This design is typically represented as follows:

$$O_1 \quad X \quad O_2$$

where O_1 represents the pretest, X represents some treatment, and O_2 represents the posttest.

Including a pretest measure is an improvement over the posttest-only research design; however, this design is still relatively weak in terms of internal validity. Although this design allows researchers to examine some outcome of interest prior to some treatment (O_1),

it does not eliminate the possibility that O_2 might have occurred regardless of the treatment. For example, threats to internal validity, such as maturation, history, and testing, could be responsible for any observed difference between the pretest and posttest. Also, the longer the time lapse between the pretest and posttest, the harder it is to rule out alternative explanations for any observed differences.

When the outcome of interest is continuous, data obtained from the one-group pretest–posttest design can be analyzed with the dependent-means t test (also sometimes called the correlated-means t test or the paired-difference t test), which tests $H_0 : \mu_D = 0$. When the outcome of interest is categorical and has only two levels, one-group pretest–posttest data can be analyzed with McNemar's chi-square to test the null hypothesis that the distribution of responses is the same across time periods. However, when the outcome of interest is categorical and has more than two levels, McNemar's chi-square cannot be used. Instead, data can be analyzed through Mantel–Haenszel methods.

One-Group Pretest–Posttest Design Using a Double Pretest

The one-group pretest–posttest design can be improved upon by adding a second pretest prior to treatment administration:

$$O_1 \quad O_2 \quad X \quad O_3,$$

where O_1 and O_2 represent the two pretests, X represents some treatment, and O_3 represents the posttest.

Adding a second pretest to the traditional one-group pretest–posttest design can help reduce maturation and regression to the mean threats as plausible explanations for any observed differences. For example, instead of comparing O_3 only to O_1 or O_2 , any observed difference between O_2 and O_3 can also be compared to any differences between O_1 and O_2 . If the difference between O_2 and O_3 is larger than the difference between O_1 and O_2 , then the observed change is less likely solely due to maturation.

When the outcome of interest is continuous, data obtained from the one-group pretest–posttest design using a double pretest can be analyzed through a within-subject design analysis of variance (ANOVA) (also sometimes referred to as repeated measures ANOVA) with appropriate contrasts to test the null hypothesis of interest, $H_0 : \mu_{\text{post}} - \mu_{\text{pre2}} = \mu_{\text{pre2}} - \mu_{\text{pre1}}$. When the outcome of interest is categorical, data from this design can be analyzed with conditional logistic regression (also referred to as subject-specific models) to test the null hypothesis that the distribution of responses is the same across time periods.

One-Group Pretest–Posttest Design Using a Nonequivalent Dependent Variable

The simple one-group pretest–posttest design also can be improved by including a nonequivalent dependent variable. For example, instead of obtaining pretest and posttest data on the outcome of interest, with this design, the researcher obtains pretest and posttest data on the outcome of interest (A) as well as on some other outcome (B) that is similar to the outcome of interest but is not expected to change based on the treatment.

$$(O_{1A}, O_{1B}) \quad X \quad (O_{2A}, O_{2B}).$$

In this design, O_{1A} represents the pretest on the outcome of interest, O_{1B} represents the pretest on the nonequivalent outcome, X represents some treatment, O_{2A} represents the posttest on the outcome of interest, and O_{2B} represents the posttest on the nonequivalent outcome. Including a nonequivalent dependent variable helps researchers assess any naturally occurring trends in the data, separate from the treatment effect. If the posttest difference for the outcome of interest ($O_{2A} - O_{1A}$) is larger than the posttest difference for the secondary outcome ($O_{2B} - O_{1B}$), the less likely the change is solely a result of maturation.

When the outcome of interest is continuous, data obtained from the one-group pretest–posttest design using a nonequivalent dependent variable can be analyzed through a within-subject ANOVA design with appropriate contrast statements to test the null hypothesis of interest, $H_0 : \mu_{\text{postA}} - \mu_{\text{preA}} = \mu_{\text{postB}} - \mu_{\text{preA}}$. When the outcome of interest is categorical, data from this design can be analyzed with conditional logistic regression to test the null hypothesis that the distribution of responses is the same across time periods and across the two dependent variables (i.e., outcome of interest and the nonequivalent dependent variable).

Removed-Treatment Design

This design is also an improvement to the one-group pretest–posttest design. By adding multiple posttests and the removal of the treatment to the one-group pretest–posttest design, the removed-treatment design allows better control over the internal validity of a study. That is, by examining the outcome of interest after the treatment has been stopped or removed, researchers have another piece of information that allows for multiple comparisons and helps inform their conclusions. This design is typically represented as

$$O_1 \quad X \quad O_2 \quad O_3 \quad -X \quad O_4,$$

where O_1 represents the pretest on some outcome of interest, X represents some treatment, O_2 represents the

first posttest on the outcome of interest, O_3 represents the second posttest on the same outcome of interest, $-X$ represents treatment removal, and O_4 represents the third posttest on the outcome of interest.

With this design, if a treatment effect exists, the difference between O_2 and O_1 should be greater than the difference between O_4 and O_3 . Also, examining changes between O_3 and O_2 allows the researcher to investigate possible trend effects after treatment. However, this theoretical pattern of change is often difficult to observe unless a treatment effect dissipates quickly upon treatment removal (which is often not the case in the social and behavioral sciences). Furthermore, because removal of certain treatments might be considered unethical, considerations need to be discussed before employing this pretest–posttest design.

When the outcome of interest is continuous, data obtained from the removed-treatment design can be analyzed through a within-subject ANOVA with appropriate contrast statements to test the null hypothesis of interest, $H_0 : \mu_{\text{post1}} - \mu_{\text{pre}} = \mu_{\text{post3}} - \mu_{\text{post2}}$. When the outcome of interest is categorical, data from this design can be analyzed with conditional logistic regression to test the null hypothesis that the distribution of responses is the same across time periods.

Repeated-Treatment Design

Building upon the removed-treatment design, the repeated-treatment design includes multiple posttest observations, treatment removal, and treatment reintroduction. In the following notation, O_1 represents the pretest on some outcome of interest, X represents some treatment, O_2 represents the first posttest on the outcome of interest, $-X$ represents treatment removal, O_3 represents the second posttest on the same outcome of interest, and O_4 represents the third posttest on the outcome of interest.

$$O_1 \quad X \quad O_2 \quad \times \quad O_3 \quad X \quad O_4.$$

If a treatment effect is present, in this design, O_2 should differ from O_1 and from O_3 ; however, the difference between O_3 and O_2 should be opposite or less than the difference between O_2 and O_1 . Similarly, O_4 should differ from O_3 , and the difference between O_4 and O_3 should be similar to the difference between O_2 and O_1 . Although the inclusion of a second treatment period adds rigor to this design, it is not without limitations. As with the removed-treatment design, this design is best when the treatment effect will truly dissipate upon removal of the treatment and when it is ethically acceptable to remove the treatment. Furthermore, by reintroducing the treatment, participants are more likely to become aware of the treatment and

researchers' expectations, thus increasing the potential of contamination.

When the outcome of interest is continuous, data obtained from the repeated-treatment design can be analyzed through a within-subject design ANOVA with appropriate contrast statements to test the null hypotheses of interest, $H_0 : \mu_{\text{post1}} - \mu_{\text{pre}} = \mu_{\text{post2}} - \mu_{\text{post1}}$ and $H_0 : \mu_{\text{post2}} - \mu_{\text{post1}} = \mu_{\text{post3}} - \mu_{\text{post2}}$. When the outcome of interest is categorical, data from this design can be analyzed with conditional logistic regression to test the null hypothesis that the distribution of responses is the same across time periods.

Types of Pretest–Posttest Designs With Control Groups

Two-Group Pretest–Posttest Design

Similar to the one-group pretest–posttest design, this design includes a nontreated control group and is often represented as follows:

$$O_1 \quad X \quad O_2$$

$$O_1 \quad X \quad O_2,$$

where O_1 represents the pretest, X represents some treatment, and O_2 represents the posttest. When randomization is employed, the two-group pretest–posttest design becomes the classic experimental design.

Whether the two-group pretest–posttest design is used in experimental or quasi-experimental research, including an untreated control group reduces threats to internal validity and allows for within-group and between-group comparisons. For example, although selection bias is still a concern when this design is used in quasi-experimental research, use of a pretest and a comparison group allows researchers to examine the nature and extent of selection bias by comparing the treatment and control groups before the treatment is administered. Noting any pretest differences between the groups allows for stronger inferences to be made after the treatment is administered. Also, although threats such as maturation and history still might exist with the two-group pretest–posttest design, the effects of these threats should be the same for both groups, thus adding more support for a treatment effect when observed posttest differences exist between the groups.

When the outcome of interest is continuous, data obtained from the two-group pretest–posttest design can be analyzed with a one-between one-within ANOVA design (also referred to as a factorial repeated measures ANOVA) to test $H_0 : \mu_{\text{post-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{post-C}} - \mu_{\text{pre-C}}$. When the outcome of interest is categorical, two-group pretest–posttest data can be analyzed with

generalized estimating equations (GEEs) to test the null hypothesis that the distribution of responses is the same across time periods and between groups.

Two-Group Pretest–Posttest Design With a Double Pretest

Improving upon the two-group pretest–posttest design, the two-group pretest–posttest design with a double pretest includes administering two pretests prior to treatment followed by one posttest measure after the treatment period.

$$\begin{array}{cccc} O_1 & O_2 & X & O_3 \\ O_1 & O_2 & & O_3 \end{array}$$

In this design, O_1 represents the first pretest, O_2 represents the second pretest, X represents some treatment, and O_3 represents the posttest. One advantage of the two-group pretest–posttest design with a double pretest over the two-group pretest–posttest design is the ability to examine trends and selection bias in the treatment and control groups prior to treatment administration. If the treatment has an effect, the change between O_3 and O_2 for the treatment group should be different from the observed change during the same time period for the control group. This design also reduces threats to internal validity. By including the untreated control group, threats such as maturation, history, and regression to the mean would occur in both groups, thus, in essence, balancing the groups in terms of threats. Therefore, observed pretest–posttest treatment group differences are more likely to represent treatment effects.

When the outcome of interest is continuous, data obtained from the two-group pretest–posttest design with a double pretest can be analyzed with a one-between one-within ANOVA design with appropriate contrast statements to test the null hypothesis of interest, $H_0: \mu_{\text{post-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{post-C}} - \mu_{\text{pre-C}}$. When the outcome of interest is categorical, data from this design can be analyzed with GEEs with appropriate contrast statements to test the null hypothesis, $H_0: \mu_{\text{post-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{post-C}} - \mu_{\text{pre-C}}$.

Four-Group Design With Pretest–Posttest and Posttest–Only Groups

Also known as the Solomon four-group design, this design is a combination of the two-group pretest–posttest design and the two-group posttest-only design. Pretest measures are obtained from the two pretest–posttest groups, treatment is administered to one of the

pretest–posttest groups and to one of the posttest-only groups, and posttest measures are obtained from all four groups.

$$\begin{array}{cccc} O_1 & X & O_2 & \\ O_1 & & O_2 & \\ & X & O_2 & \\ & & O_2 & \end{array}$$

In this design, O_1 represents the pretest, X represents some treatment, and O_2 represents the posttest.

Although this design is a bit more complicated than the simple two-group pretest–posttest design, the inclusion of the two posttest-only groups allows researchers to investigate possible testing threats to internal validity. For example, if O_2 for the treatment pretest–posttest group is similar to O_2 for the treatment posttest-only group, then testing effects are likely not present. Similarly, as with other multiple-group pretest–posttest designs, this design allows for both within-group and between-group comparisons, including examination of possible selection bias when this design is used in quasi-experimental research. With this design, maturation and history threats to internal validity are also diminished. If a treatment effect is present, then the difference between O_2 and O_1 should be the same for the treatment and control pretest–posttest groups, and O_2 for the two treatment groups should be similar to one another and different from O_2 for the two control groups.

When the outcome of interest is continuous, data obtained from the Solomon four-group design can be analyzed with two different statistical procedures. First, a one-between one-within ANOVA design can be used to test the null hypothesis, $H_0: \mu_{\text{post-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{post-C}} - \mu_{\text{pre-C}}$ and an independent means t test can be used to test the null hypothesis $H_0: \mu_{\text{post-Tx2}} - \mu_{\text{post-C2}}$. When the outcome of interest is categorical, data can be analyzed with GEEs to test analogous null hypotheses: $H_0: \mu_{\text{post-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{post-C}} - \mu_{\text{pre-C}}$ and $H_0: \mu_{\text{post-Tx2}} - \mu_{\text{post-C2}}$.

Switching Replications Design

The switching replications design refers to the process of obtaining pretest data from two groups, administering some treatment to one group, obtaining a second assessment measure from both groups, administering the same treatment to the second group, and obtaining a third assessment measure from both groups. This design is typically denoted as

$$\begin{array}{cccc} O_1 & X & O_2 & O_3, \\ O_1 & & O_2 & X & O_3 \end{array}$$

where O_1 refers to the pretest assessment for both groups, X represents some treatment, O_2 represents the first posttest for the first group and the second pretest for the second group, and O_3 represents a second posttest for the first group and the first posttest for the second group.

As with the other pretest–posttest designs that use a control group, if participants are not randomly assigned to the groups, selection bias is a likely threat. However, because pretest measures are obtained from both groups, potential group differences can be examined before the first treatment is administered. Furthermore, administering the treatment to both groups at different times helps improve the internal validity of the study. For example, if some trend were responsible for any observed difference between O_2 and O_1 for the first group, then one also would expect to see the same level of change during this time period in the second group. This same principle applies to differences between O_3 and O_2 . Thus, if a treatment effect exists, the difference between O_2 and O_1 for the first group should be different from the difference between O_2 and O_1 for the second group, yet similar to the difference between O_3 and O_2 for the second group. However, as with the four-group design with pretest–posttest and posttest-only groups, the timing difference in treatment administration is an important issue that needs to be acknowledged when employing this design. The treatment administration to the second group can never be exactly the same as the treatment that is administered to the first group.

When the outcome of interest is continuous, data obtained from the switching replications design can be analyzed with a one-between one-within ANOVA design with appropriate contrast statements to test the null hypotheses of interest, $H_0: \mu_{\text{post1-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{pre2-C}} - \mu_{\text{pre1-C}}$ and $H_0: \mu_{\text{post2-Tx}} - \mu_{\text{post1-Tx}} = \mu_{\text{post2-C}} - \mu_{\text{pre2-C}}$. When the outcome of interest is categorical, data from this design can be analyzed using GEEs and analogous contrasts as those above to test the null hypotheses of interest, $H_0: \mu_{\text{post1-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{pre2-C}} - \mu_{\text{pre1-C}}$ and $H_0: \mu_{\text{post2-Tx}} - \mu_{\text{post1-Tx}} = \mu_{\text{post2-C}} - \mu_{\text{pre2-C}}$.

Reversed-Treatment Pretest–Posttest Control Group Design

With this design, one group receives the treatment of interest, expected to affect the outcome of interest in one direction, and the other group receives an opposite treatment, expected to affect the outcome of interest in the opposite direction. Diagrammed as

$$O_1 \quad X_+ \quad O_2$$

$$O_1 \quad X_- \quad O_2$$

O_1 represents the pretest, X_+ represents the treatment of interest, X_- represents the treatment expected to produce opposite effects, and O_2 represents the posttest.

The basic premise behind this design is that if the difference between O_2 and O_1 for the group administered X_+ is in one direction and the difference between O_2 and O_1 for the group administered X_- is in the opposite direction, a statistical interaction, suggesting a treatment effect, should be present. However, as with the other pretest–posttest designs that use a control group, if participants are not randomly assigned to the groups, selection bias is a likely threat and should be examined. Also, as with pretest–posttest designs that include treatment removal or delayed treatment administration, ethical issues often surround use of the reversed-treatment pretest–posttest control group design. Finally, conceptual difficulties are inherent in such a design as researchers must identify treatments that are expected to produce opposite effects on the outcome variable.

When the outcome of interest is continuous, data obtained from the switching replications design can be analyzed with a one-between one-within ANOVA design to test the null hypothesis of interest, $H_0: \mu_{\text{post-Tx}} - \mu_{\text{pre-Tx}} = \mu_{\text{post-C}} - \mu_{\text{pre-C}}$. When the outcome of interest is categorical, data can be analyzed with GEEs to test the null hypothesis that the distribution of responses is the same across time periods and between groups.

PRIMARY DATA SOURCE

A primary data source is an original data source, that is, one in which the data are collected firsthand by the researcher for a specific research purpose or project.

Primary data can be collected in a number of ways. However, the most common techniques are self-administered surveys, interviews, field observation, and experiments. Primary data collection is quite expensive and time consuming compared to secondary data collection. Notwithstanding, primary data collection may be the only suitable method for some types of research.

Primary Data Sources Versus Secondary Data Sources

In the conduct of research, researchers rely on two kinds of data sources—primary and secondary. The term *primary source* is used broadly to embody all sources that are original. This can be contrasted with the term *primary data source*, which refers specifically to the firsthand collection of data for a particular purpose. In the context of the broader definition, primary sources may be published (e.g., census data) or unpublished (e.g., President Lincoln's personal diary), and could be from the past (e.g., artifacts) or present (e.g., poll for a national election). In many types of research, these sources are often created at the time of the event for a specific purpose (e.g., President Obama's inauguration speech, a company's marketing survey of 2009 teenage fashions). However, primary sources may also encompass records of events as described by an eyewitness to the event or someone who actually experienced the event. Both primary data sources and primary sources provide firsthand, unmediated information that is closest to the object of study. This is not a guarantee, however, that these sources are always accurate. For example, if data are collected via face-to-face interviews, the data quality may be affected by a number of issues, such as interviewee characteristics, data transcription, data entry, and so on. Likewise, when eyewitness accounts are given, they can be deliberately or unconsciously distorted.

The delineation of primary and secondary sources first arose in the field of historiography, when historians attempted to classify sources of handwriting. Over time, various disciplines have attempted to normalize the definition for *primary* and *secondary* sources. However, these two classifications remain highly subjective and relative. This is because these terms are highly contextual. A particular source may be considered as either primary or secondary depending on the context in which it is examined.

Primary data sources are most often created using survey research. There are a number of different survey techniques that can be used to collect primary data, such as interviews (e.g., face-to-face, telephone, e-mail, fax) or self-administered questionnaires. When polls, censuses, and other direct data collection are

undertaken, these all constitute primary data sources. However, when these sources are subsequently used by others for other research purposes, they are referred to as secondary data sources. Primary data sources may also be created using other methods, such as field observation and experiments (e.g., pretests and test marketing). The latter technique is particularly important in marketing research projects and can be done in either a laboratory or a field setting. In contrast, some common examples of primary sources include speeches, letters, diaries, autobiographies, interviews, official reports, legislation, court records, tax records, birth records, wills, newsreels, artifacts, poetry, drama, films, music, visual art, paintings, photographs, and drawings, along with all those sources that are classified as primary data sources.

Comparatively, a secondary data source refers to a data source that is already in existence (e.g., Gallup, Harris, and Roper polls; General Social Survey; national census) and is being used either for a purpose for which it was not originally intended and/or by someone other than the researcher who collected the original data. Such sources are considered to be nonoriginal or secondhand, but are nonetheless considered to be quite valuable. They are generally obtained from public archives (e.g., Inter-University Consortium for Political and Social Research maintained at the University of Michigan, National Network of State Polls maintained at the University of North Carolina) but may also be obtained from other researchers or even from a researcher's previous work. Public archives can be accessed and used by researchers either free of cost or for a small fee. The significant cost savings that can result from use of secondary data sources is perhaps one of the greatest attractions of using secondary data. Other advantages include greater efficiency (easier to obtain, less time required) and strengthened confidence (triangulation of primary and secondary sources or multiple secondary sources). However, the challenges associated with secondary data sources, which are discussed later, may far outweigh these benefits. Notwithstanding, these sources are invaluable in certain types of research (e.g., historical and comparative research), and their use, particularly in the United States, has increased substantially over the past 25 years.

The Need for Primary Data

Researchers collect data for numerous reasons. It may be to answer a particular research question, solve a particular problem, test some hypothesis, validate or falsify an existing theory, better understand some phenomenon, write a report or research paper, write a thesis or dissertation, or perhaps simply for the sake of

learning/knowledge. Regardless of the reason, data collection generally requires a systematic and purposeful approach that is largely determined by the research design best suited to achieve the research objectives. In other words, the research design specifies the type of data that is to be collected, the population and other sources from which the data will be collected, and the procedures that will be used to collect the data.

There are several reasons why researchers may choose to use a primary rather than a secondary data source when conducting research.

Primary data sources undoubtedly constitute the purest form of data—these sources are firsthand and unfiltered. As such, primary data sources may be the preferred choice in many types of research, particularly those pertaining to scholarship, where credibility might be questioned if only secondary data sources were used. Additionally, in some types of research such as historical writing, many historians believe that objective connection to the past cannot be captured with secondary sources.

Aggregated data are often not sufficiently detailed to serve the needs of certain types of research, and differences in units of measurement may further complicate the problem. For example, if a researcher is conducting research at a rural community level, but is using data collected at the country level (e.g., census data), it would be difficult and/or impossible to draw any conclusions at the rural community level unless rural community data could be extracted accurately and the researcher could actually get access to these data. If this is not possible, the researcher would need to gather primary data at the community level to conduct the particular study. Likewise, if a marketing study is being targeted to a particular trade area, but data are aggregated at the town or country level, these data would not be suitable and primary data would need to be collected.

Regardless of whether researchers can get access to more detailed data, they still need to be concerned about data quality. The greatest challenge associated with a secondary data source pertains to uncertainty about data collection processes. Even when data are collected by government agencies, this is no indication that the data are of high quality, accurate, or uncontaminated. In order for research to have validity and credibility, the entire research process must be sufficiently rigorous. When researchers collect primary data, they are in complete control of the data collection process. This concern is therefore considerably minimized.

Researchers may be concerned about the extent to which secondary data sources fit the information needs of the current study and the related concern of built-in bias. Data that are collected for one purpose are often not suitable for another. This is not a concern with

primary data because data collection is tailored to the specific research objectives, so intended-use bias is eliminated.

The definition of classes (e.g., age, income) may also present a problem. For example, in the United States, adults are classified by public opinion polls as persons 18 years or older. However, the specific research study may be interested in adults 21 years or older.

The age of the data may also be of concern. Research generally needs current data. However, due to cost, many national data studies are conducted only every 5 years.

No secondary data source may exist for some types of research. For example, scant data have been collected on some ethnic groups (e.g., Hispanics). Thus, if a marketing strategy is being targeted at Hispanics, primary data may be necessary because the spending patterns of Hispanics may be quite different from those of other groups.

Even if secondary data sources exist that are current, accurate, and relevant, they still may not be suitable for the particular research. For example, a secondary data source on customer appliance purchase habits would not be suitable for new product development.

Possible data distortion, which can occur when data are reused multiple times and modified by new authors, may be a concern. With primary data, distortion is not an issue because the researcher is using original data.

Thus, although secondary data sources are relatively quick and quite inexpensive to obtain, their inherent challenges need to be carefully considered. If these challenges cannot be adequately addressed, the research may produce misleading and inaccurate results. Depending on the type of research that is being conducted, researchers therefore need to answer one or more of the following questions: What were the credentials of the primary investigator? When were the data collected? For whom were the data collected? How were the variables selected? What were they supposed to measure? How was the sample selected? Were the data collection and data entry processes systematic and rigorous? Is the original data collection form available for viewing? Is there someone who can be contacted to provide more insight into the whole data collection and research process? Can less aggregated data be obtained, and what are the ethical implications?

Ethical Issues Associated With Primary Data Collection

Most types of primary data collection require the approval of an institutional review board (IRB) to ensure the adequate protection of human subjects. Many

government departments, universities, and other large institutions generally have their own IRBs. Notwithstanding, the time frame for approval may still take several weeks, especially if a researcher is asked to make changes to his or her application or instrument in order to obtain approval. When secondary data sources are used, researchers are spared the headache of gaining IRB approval. However, other ethical implications may need to be considered if researchers are given access to detailed original data. For example, should participant approval be sought when data that are collected for one purpose are being used for another?

Cost Implications of Primary Data Sources

Primary data collection is a resource-intensive activity in terms of both time and cost. Depending on the purpose for which the data are required, primary data collection may take several months—or years—to accumulate. In addition, the data collection technique chosen can have significant cost implications. For example, face-to-face interviews are considerably more expensive compared to telephone interviews or self-administered surveys because face-to-face interviews not only are longer (approximately 1 hour) but also require the use of more highly skilled interviewers who possess certain characteristics. Other significant costs associated with primary data collection include the cost of data entry and validation and the cost associated with sample selection. In contrast, when secondary data sources are used, the only cost that is generally incurred is the cost to access a database.

PRINCIPAL COMPONENTS ANALYSIS

Also known as empirical orthogonal function analysis, principal components analysis (PCA) is a multivariate data analysis technique that is employed to reduce the dimensionality of large data sets and simplify the representation of the data field under consideration. PCA is used to understand the interdependencies among variables and trim down the redundant (or significantly correlated) variables that are measuring the same construct. Data sets with a considerable proportion of interrelated variables are transformed into a set of new hypothetical variables known as principal components, which are uncorrelated or orthogonal to one another. These new variables are ordered so that the first few components retain most of the variation present in the original data matrix. The components reflect both common and unique variance of the variables (as opposed to common factor analysis that excludes unique variance), with the last few components identifying directions in which there is negligible variation or a near linear relationship with the original variables. Thus, PCA reduces the number of variables under examination and allows one to detect and recognize groups of interrelated variables. Frequently, PCA does not generate the final product and is often used in combination with other statistical techniques (e.g., cluster analysis) to uncover, model, and explain the leading multivariate relationships. The method was first introduced in 1901 by Karl Pearson and subsequently modified three decades later by Harold Hotelling for the objective of exploring correlation structures; it has since been used extensively in both the physical and social sciences.

Mathematical Origins and Matrix Constructs

PCA describes the variation in a set of multivariate data in terms of a new assemblage of variables that are uncorrelated to one another. Mathematically, the statistical method can be described briefly as a linear transformation from the original variables, $x_1, \dots, x_p$, to new variables, $y_1, \dots, y_p$ (as described succinctly by Geoff Der and Brian Everitt), where

$$y_1 = a_{11}x_1 + a_{12}x_2 + \dots + a_{1p}x_p$$

$$y_2 = a_{21}x_1 + a_{22}x_2 + \dots + a_{2p}x_p$$

$$\vdots$$

$$y_p = a_{p1}x_1 + a_{p2}x_2 + \dots + a_{pp}x_p.$$

The coefficients, a_{pp} , defining each new variable are selected in such a way that the y variables or principal

components are orthogonal, meaning that the coordinate axes are rotated such that the axes are still at right angles to each other while maximizing the variance. Each component is arranged according to decreasing order of variance accounted for in the original data matrix. The number of possible principal components is equal to the number of input variables, but not all components will be retained in the analysis seeing that a primary goal of PCA is simplification of the data matrix (see the subsequent section on principal component truncation methods).

The original coordinates of the i th data point, x_{ij} , $j = 1, \dots, p$ becomes in the new system (as explained by Trevor Bailey and Anthony Gatrell):

$$y_{ij} = a_{j1}x_{i1} + a_{j2}x_{i2} + \dots + a_{jp}x_{ip}$$

The j th new variable y_j is normally referred to as the j th principal component, whereas y_{ij} is termed the score of the i th observation on the j th principal component. The relationship between the j th principal component and the k th original variable is described by the covariance between them, given as

$$a_{jk} \sqrt{\frac{\lambda_j}{s_{kk}}},$$

where s_{kk} is the estimated variance of the k th original variable or the k th diagonal element of the data matrix S . This relationship is referred to as a loading of the k th original variable of the j th principal component. Component loadings are essentially correlations between the variables and the component and are interpreted similarly to product-moment correlation coefficients (or Pearson's r). Values of components loadings range from -1.0 to 1.0 . More positive (negative) component loadings indicate a stronger linkage of a variable on a particular component, and those values closer to zero signify that the variable is not being represented by that component.

In matrix algebra form, the set of uncorrelated variables is derived by a set of linear transformations, E , where

$$\Lambda = E^T (Z^T Z) E.$$

Matrix E is the eigenvector matrix extracted from the observed correlation matrix, R , and Λ is the diagonal matrix of the eigenvalues, λ_i . The eigenvalue for component i , λ_i , is computed as

$$\lambda_i = \sum_{j=1}^n L_{ij}^2,$$

where L_{ij} is the loading for variable j on component i . It is the sum of the squared loadings that indicates the

total variance accounted for by the component in each of the new direction components axes. Each squared component loading signifies the extent to which the new variable or component number is able to characterize the attributes of the original variable. Higher (lower) eigenvalues indicate a larger (smaller) proportion of the total variance. Generally, eigenvalues greater than 1.0 will collectively provide a fitting and efficient description of the data, and thereby reduce the original variable set to a few new hypothetical variables, the principal components.

PCA operates in one of several analytic modes (as outlined by G. David Garson) depending on the data structure or rather the relative positioning of the cases and variables in the data matrix. The most widespread is R-mode, which identifies clusters of variables (the columns) based on a set of cases (the rows) for a given moment in time. R-mode is often the default setting in many statistical packages (e.g., SPSS, an IBM company) and not usually specifically identified as such. In contrast, Q-mode clusters the cases rather than variables and accordingly reverses the row and column inputs of the R-mode. The emphasis in Q-mode is on examining how the cases cluster on particular components and determining if a separation exists among cases based on a positive or negative loading response. Consequently, Q-mode analysis is frequently regarded as a clustering analysis technique and is sometimes used in place of traditional cluster analysis methods (e.g., agglomerative hierarchical cluster analysis).

Other, less common PCA analytic modes include S-mode, T-mode, and O-mode. These modes are usually reserved for PCA involving an extended time period (e.g., several weeks) rather than a single, indeterminate measurement time. In an S-mode data structure, the time component comprises the cases (the rows), the specific data points are the columns, and the individual cells contain information on a single variable. The components produced from an S-mode analysis would demonstrate how these data points cluster together on a variable over time. Spatial data typically have an S-mode construct, where geographically oriented variables (e.g., the daily maximum temperature per station) are examined for similar regional modes of variability across the record period. Alternatively, O-mode PCA analysis looks into time periods that show data points exhibiting similar variances on a particular set of measures. The O-mode PCA structure functions similar to a time series analysis by examining how the time element (the columns) clusters on each component according to a variable set (the rows) for a single case. Like O-mode PCA analysis, the T-mode construct also places emphasis on clustering time on each of the components (the columns), except that information is

gathered on a single variable for multiple cases (the rows). The T-mode PCA structure is particularly useful for investigating whether or not differences for a particular variable exist between two or more time periods.

As with all statistical techniques, PCA has a set of requirements and assumptions to be met prior to application. The data set under examination should contain no outliers, lack or diminish selection bias, and assume interval- or ratio-level data with multivariate normality. Furthermore, the underlying dimensions of the input variables are shared, identified as having moderately high intercorrelations that can be determined using Kaiser-Meyer-Olkin (KMO) test statistics. The KMO test statistic of sampling adequacy, based on correlation and partial correlation of the variables, predicts the likelihood that PCA is a viable data reduction technique and will produce meaningful components. The KMO ranges from 0 to 1.0 and should be about 0.60 or higher to proceed with the PCA. In addition to the KMO, Bartlett's Test of Sphericity (BTS) may also be used to determine if PCA is an appropriate statistical method. BTS tests the hypothesis that the data correlation matrix is an identity matrix, indicating the variables under consideration are unrelated and, hence, inappropriate for structure detection. A BTS test result with a significance level value of 0.05 or smaller indicates that PCA may be a useful data analysis method.

Principal Component Truncation Methods

Mathematically, the number of eigenvectors produced from the analysis equals the number of variables entered into the data matrix. However, because a major goal of PCA is to simplify the data set while capturing the majority of its variance, the eigenvectors analyzed are often truncated. Typically, the first few principal components capture the most variance in the data set and are retained for further analysis, whereas the other components represent a small, insignificant fraction of the variability. The cumulative percentage of variation is often used to truncate the components after a set percentage threshold has been achieved; components accounting for between 70% and 90% of the total variation in the data set are retained. Several other criteria, which are often rather subjective, have also been used to determine the number of factors to retain from a PCA throughout the physical and social sciences.

One truncation method involves comparing each eigenvalue of each eigenvector to the amount of joint variance shown in the average eigenvalue. The eigenvectors retained are based on a predetermined eigenvalue threshold parameter (e.g., the lowest significant eigenvalue deemed to be meaningful). Commonly,

Kaiser's rule is applied, which states that all components with eigenvalues less than 1.0 should be eliminated from the analysis. The rationale behind the Kaiser criterion is that eigenvalues less than 1.0 account for less of the total variance than did any one of the original variables; however, in some cases, it is desirable to select a minimum value lower than 1.0 to allow for sampling variation and a more liberal eigenvalue threshold. For instance, I. T. Jolliffe suggests removing all components with eigenvalues less than 0.7, which can substantially increase the number of retained components and diminish the data reduction capability of PCA.

Graphically based selection methods have the researcher truncate the number of components based on a qualitative assessment of an eigenvalue spectrum plot (i.e., displaying the eigenvalues in descending order). Two such methods are the Cattell scree test (or simply scree plot) and the log-eigenvalue diagram. The scree plot charts the component number (x -axis) against the eigenvalues (y -axis). Likewise, the log-eigenvalue diagram shows the eigenvalue magnitude as a function of the principal component number, but with a logarithmic transformation to emphasize an exponential drop in the size of the eigenvalues. In both charts, the researcher subjectively examines the plot for a steep decline in the eigenvalues from which there is a flattening of the curve; components immediately prior to the straightening of the curve are retained. The absence of a significant decline or elbow shape to the curve indicates that more than the first few components are needed to adequately represent the variance in the data set.

Communality is also a good indicator of the reliability of the model and the appropriate number of components to keep. It is the squared multiple correlation for a variable using the components as predictors so that

$$h_j^2 = \sum_{i=1}^k L_{ij}^2,$$

where L_{ij} is the loading for variable j on component i , k is the number of components ($\leq n$), and h_j^2 is the communality for variable j . The resulting value specifies the proportion of variance accounted for by a particular set of components. Communalities generally range from 0 to 1, where low values indicate that either the variable is not functioning well in the PCA model or additional components need to be extracted in order to capture the variability for that element. Hence, communalities can indicate if an initial truncation was too severe and a more liberal selection criterion should be applied.

In practice, no single truncation method works for all situations, and often, several trials are needed before the final selection of the number of factors to retain is made. For instance, Kaiser's rule typically retains far too many components and does not adequately simplify the data matrix, especially with an increasing number of input variables. On the other hand, the scree test may retain few components, especially if the first eigenvalue is heavily loaded on the first one or two components. Truncation methods will usually produce the most comparable results when the number of data elements is relatively small in comparison to the number of cases. Moreover, determining the number of components to use is not solely based on obtaining a large proportion of the variance and having each retained component be a significant contributor. The researcher must decide if the retained components are interpretable or meaningful while providing a parsimonious description of the data.

Eigenvector Rotation

By definition, the eigenvectors produced from PCA are orthogonal to one another, resulting in uncorrelated principal components. This restraint can make interpretation of the principal components difficult, particularly for fields involving fundamental processes that are not mutually exclusive. For example, data sets with a spatial component (e.g., geographical coordinates) often contain elements that are interrelated to one another by virtue of position, such as the temperature of one location being heavily influenced by the temperature, moisture, wind direction, terrain, and so on, of adjacent locations. Although the first component may contain a significant proportion of the variability of a data set, a single process may not actually be represented by the first component and may contain information representing several separate processes that are then difficult to partition out. Hence, unrotated solutions tend to have variables that load on multiple components. The purpose of rotation is to simplify the principal component coefficients and facilitate understanding the primary modes of variability. Rotating the eigenvectors is mainly appropriate when physical interpretation rather than data matrix reduction is the most important result from the PCA.

In nearly all computer statistical packages (e.g., SPSS), the default for PCA is an unrotated solution that will be produced in addition to any selected rotation. Unrotated components will show the maximum variance on the first component, with eigenvalues and associated variance decreasing with each increasing component. In a rotated PCA, the cumulative variance (and same total eigenvalue) produced by the retained

principal components remains the same as in the unrotated solution, but the loadings across the individual components change. Accordingly, the first rotated principal component will most likely not represent the maximum variance in the data set.

Rotation methods fall into two main types, orthogonal and oblique, depending on the relative orientation of the eigenvectors. In orthogonal rotation, the eigenvectors are at right angles to one another and remain uncorrelated as in the unrotated PCA. Varimax rotation is the most widespread orthogonal rotation method and seeks to maximize the variance of the squared loadings of a component on all the variables in the component matrix. In other words, the number of variables loading on one component is minimized. On the contrary, oblique rotation techniques produce eigenvectors that are no longer at right angles to one another, thus removing the uncorrelated property between eigenvectors. Direct oblimin and Promax are both oblique methods that usually will simplify the component solution and produce higher eigenvalues in comparison to orthogonal methods; however, interpretability is somewhat diminished.

The decision to rotate the components is often highly dependent on the data structure and individual preference. The usage of the rotated and nonrotated principal components is equally prevalent in the literature and reflects the division within the scientific community. Rotated principal components often are more likely to produce physically meaningful patterns from the data and are more statistically stable, being less sensitive to sampling distribution. Yet as I. T. Jolliffe points out, applying rotation on the principal components has several negative aspects, such as the subjective selection of rotation criterion and method or the sensitivity of the result to the number of original components retained. In particular, a large drawback of rotated PCA often cited is that the interpretation of the components is highly dependent on the rotation method itself, with each rotation method resulting in new possible explanations. Furthermore, rotation also redistributes the eigenvalues, such that the first few components will no longer consecutively account for the maximum possible variation. Rotated components are usually preferred when difficulty arises in assigning physical meaning to the original retained components, particularly in cases in which the PCA is the terminus of the analysis. Generally, if a large difference in the individual component variance totals is observed between the initial PCA and the rotated PCA, then the rotated component matrix will probably have a more straightforward interpretation than the unrotated matrix.

PROBABILISTIC MODELS FOR SOME INTELLIGENCE AND ATTAINMENT TESTS

Often in social science research, data are collected from a number of examinees that are each scored on their performance on items of a test. Here, a “test” broadly refers to an assessment of an examinee’s level of ability in a particular domain such as math or reading, or a survey of an examinee’s behaviors or attitudes toward something. In *Probabilistic Models for Some Intelligence and Attainment Tests*, George Rasch proposed a model for analyzing such test data. The model, known as the Rasch model, and its extensions are perhaps among the most known models for the analysis of test data. In the analysis of data with a Rasch model, the aim is to measure each examinee’s level of a latent trait (e.g., math ability, attitude toward capital punishment)

that underlies his or her scores on items of a test. This entry takes a closer look at the Rasch model proposed in *Probabilistic Models for Some Intelligence and Attainment Tests* and its extensions.

Suppose that items of a test are each scored on two levels, say 0 = Incorrect and 1 = Correct, or 0 = False and 1 = True. The Rasch model can be represented by

$$\Pr[X_{ij} = 1 | \theta_i, \delta_j] = G(\theta_i - \delta_j), \quad (1)$$

where X_{ij} is a random variable for the score of examinee i ($i = 1, \dots, n$) on the j th item of the test ($j = 1, \dots, J$), θ_i is the latent trait parameter of the i th examinee, and δ_j is the difficulty parameter of the j th test item. Also, $G(\eta)$ is a cumulative distribution function (c.d.f.), usually assumed to be the c.d.f. of the standard logistic distribution defined by $G(\eta) = \frac{\exp(\eta)}{1 + \exp(\eta)}$,

although another popular choice, G , is the standard normal c.d.f., with $G(\eta) = \text{Normal}(\eta|0,1)$. A Rasch model that assumes G to be a standard logistic distribution or a standard normal distribution is called a logistic Rasch model or a normal-ogive Rasch model, respectively.

Many tests contain items that are scored on more than two levels. Suppose that the j th item of a test has possible scores denoted by $k = 0, 1, \dots, m_j$ for all test items indexed by $j = 1, \dots, J$. The Rasch partial credit model provides an approach to analyze test items scored on multiple levels, given by

$$\begin{aligned} \Pr[X_{ij} = k | \theta_i, \delta_{jk}, k = 1, \dots, m_j] \\ = \frac{\prod_{h=0}^k G(\theta_i - \delta_{jh}) \prod_{l=k+1}^{m_j} [1 - G(\theta_i - \delta_{jl})]}{\sum_{y=0}^{m_j} \prod_{h=0}^y G(\theta_i - \delta_{jh}) \prod_{l=y+1}^{m_j} [1 - G(\theta_i - \delta_{jl})]}, \end{aligned} \quad (2)$$

for examinees $i = 1, \dots, n$ and test items indexed by $j = 1, \dots, J$, where δ_{jk} represents the difficulty of attaining the k th score level in item j [fixing $G(\theta_i - \delta_{j0}) \equiv 1$, for all $j = 1, \dots, J$]. The Rasch rating scale model is a special case of the partial credit model, where it is assumed that all items of a test are scored on the same number of levels, with the levels having difficulties that are the same across items, that is, $m_j = m$ (>1) and $\delta_{jk} = \tau_k$ for all test items $j = 1, \dots, J$ and all score levels $k = 0, 1, \dots, m$. Note also that the Rasch model for two-level items, presented in Equation 1, is also a special case of the partial credit model, where $m_j = 1$ and $\delta_{jk} = \delta_j$ for all test items $j = 1, \dots, J$. Henceforth, to maintain simplicity in discussion, the item parameters of a Rasch model are represented by δ_{jk} (for all $k = 1, \dots, m_j$ and all $j = 1, \dots, J$), with the understanding

that δ_{jk} has a specific form for either the dichotomous, partial credit model, or rating scale Rasch model, as mentioned.

There are many ways to extend and increase the flexibility of the Rasch model, and a few of them are mentioned here. For example, the data analyst can incorporate predictor variables (e.g., the gender of the examinee, or the time that the item was administered, or the judge who rated the examinee), and specify $G(\theta_i - \delta_{jk} + \beta_1 x_{1i} + \dots + \beta_p x_{pi})$ in the model. Also, the multidimensional random coefficients multinomial logit model provides a general class of extended Rasch models that can be used to parameterize multidimensional examinee latent traits or multidimensional items. Furthermore, it is assumed that each examinee falls into one of a number of latent classes in a population indexed by $c = 1, \dots, C$, so it is possible to extend to a latent-class Rasch model by taking $G(\theta_{ic} - \delta_{jkc})$, with θ_{ic} the examinee latent trait and δ_{jkc} the item parameter in the c th latent class. Alternatively, using ideas of Bayesian inference, it is also possible to conduct a latent-class Rasch analysis, without assuming that the number of groups C is known a priori, by taking $G(\theta_{ij} - \delta_{jic})$, with the distribution of the examinee and/or item parameters modeled nonparametrically with a Dirichlet process prior distribution. Finally, instead of assuming that G is a fixed and known monotonic function (e.g., logistic c.d.f.), as is done with all the Rasch models and extensions mentioned above, a more flexible Rasch model can be defined by modeling the c.d.f. G nonparametrically as an unknown parameter, by specifying a nonparametric prior distribution on G , such as the Dirichlet process prior.

Given a sample of test data, there are several ways to estimate the (population) parameters of a Rasch model. Let ω denote the vector of all parameters in a given Rasch model. Although maximum likelihood estimation can be used to obtain a point-estimate $\hat{\omega}$, it does not yield a consistent estimate because in the Rasch model, the number of examinee parameters grows with the sample size. This problem is addressed by either one of two estimation methods that each eliminate examinee parameters and find maximum likelihood estimates of the remaining parameters of the model. The first method is marginal maximum likelihood estimation, where the examinee latent trait parameters are eliminated by marginalizing over an assumed normal distribution of latent traits in the population. The second method is conditional maximum likelihood estimation, where the latent trait parameter of each examinee is eliminated by conditioning on his or her total test score (a sufficient statistic in the Rasch model). Finally, through the use of Bayes's theorem, estimation of the Rasch model is carried out

through inference of the full posterior distribution of ω , which is based on a prior distribution on ω that is updated by the observed data.

PROBABILITY SAMPLING

In many scientific inquiries, it is impossible to individually appraise all the elements that comprise a population of interest. Instead, there is a need to infer collective properties of the whole population from a select subset of its elements. Probability sampling is an approach to selecting elements from a fixed population in such a way that

1. elements are selected by a random process,
2. every element has a nonzero chance of selection, and

3. the relative frequency with which an element is included in a sample is deducible.

A collection of elements drawn in such a way is referred to as a probability sample. The first condition imparts a degree of objectivity to a probability sample and, in combination with the other two conditions, secures a basis for statistical inferences concerning descriptive parameters of the population. It is also largely because its integrity rests on these conditions of the selection process, rather than on the acuity of the investigator, that probability sampling is so widely adopted in modern scientific and statistical surveys.

Sample Selection

In probability sampling, the selection probabilities of individual population elements and the algorithm with which these are randomly selected are specified by a sampling design. In turn, to apply a sampling design requires a device or frame that delineates the extent of the population of interest. A population often can be sampled directly using a list frame that identifies all the elements in that population, as when the names of all students in a district are registered on school records. If a list frame is available, a probability sample can be formed as each of a string of random numbers generated in accordance with a design is matched to an element or cluster of elements in the population. By contrast, some populations can be framed only by their spatial boundaries. For example, many natural resource populations can be delineated only by the tracts of land over (or under) which they are dispersed. Such a population must be surveyed indirectly via a probability sampling of coordinate locations within its spatial domain. Regardless of how a population is framed, however, the frame must be complete in the sense that it includes the entirety of the population. Inasmuch as any fraction of the population omitted from the frame will have zero probability of being selected, the frame ultimately fixes the population to which probability sampling inferences apply.

In some applications, once a design is chosen, the set of all selectable probability samples can be discerned together with the relative frequency with which each sample will be drawn. In other cases, the size of the population is never known and one cannot calculate even the number of possible samples. Nevertheless, when a valid probability sampling design is employed, at a minimum it is possible to derive the inclusion probabilities of the elements ultimately selected. The inclusion probability of an element is the relative frequency with which it is included in the observation set. Some probability sampling designs prescribe equal inclusion

probabilities for all elements, but most allow for variation across the population. Designs of the latter variety intrinsically favor the selection of certain elements or classes of elements but only to an extent that can be discerned from the relative magnitudes of the elements' inclusion probabilities.

Notably, even where a design skews the inclusion probabilities toward a certain class of elements, random selection precludes both the investigator (and the elements themselves) from directly influencing the composition of a probability sample. To underscore this point, it is informative to contrast probability sampling with non-probability sampling methods, such as purposive or quota sampling. In these strategies, the investigator plays a direct role in the selection process, often with the aim of assembling a sample that is in some sense representative or typical of the population. By definition, population elements are not drawn objectively, and the likelihood of having observed one element as opposed to another is inscrutable. A non-probability sample can yield an estimate that is close in value to a particular population parameter, but because of its discretionary nature, the selection process provides no basis for assessing the potential error of that estimate. In counterpoint, probability sampling is not designed to select representative samples, save in the weak sense of allowing every element a nonzero probability of being observed. Probability sampling is instead formulated to objectify the selection process so as to permit valid assessments of the distribution of sample-based estimates.

Estimation and Inference

Applied to a given population, probability sampling admits the selection of any one of a typically large number of possible samples. As a result, a chosen parameter estimator acquires a distribution of possible values, each value corresponding to at least one selectable sample. This distribution is often referred to as the randomization distribution of an estimator because it arises from the random selection process. In practice, an estimator takes only one value when applied to the sample data actually collected, but this singular estimate is nonetheless a realization of the randomization distribution induced by the sample design.

The properties of an estimator's randomization distribution are conditioned by various aspects of the population being sampled but are also controlled by the sampling design. Indeed, an advantage of probability sampling is that the character and degree of variability in an estimator's randomization distribution often can be derived from the sampling design and the estimator's algebraic form. In particular, without

setting conditions on the structure of the population, one can generally specify estimators that are unbiased for specific parameters. For example, take the Horvitz–Thompson estimator,

$$\hat{\theta} = \sum_{k \in s} \frac{y_k}{\pi_k},$$

which expands the attribute measurement y_k made on the k th distinct element in a probability sample s by that element's inclusion probability (π_k) and sums these expansions across all selected elements. This estimator is unbiased for the true population total of the y_k under any probability sampling design. Thus, to unbiasedly estimate total research expenditures in a particular sector of the economy, a probability sample of firms in that sector could be drawn and then the sum of the ratios of each firm's research outlay (y_k) to inclusion probability (π_k) could be calculated.

Modifications of the Horvitz–Thompson and other estimation rules provide unbiased estimators of population means, proportions, and distribution functions. Additionally, for many designs, unbiased estimators of the variance of these parameter estimators can be derived. Hence, with many probability sampling strategies, one can estimate population parameters of interest in an unbiased manner and attach valid measures of precision to those estimates. Going further, one can draw inferences on parameters via confidence intervals that account for the variability of the estimator, given the sampling design.

Designs

The random selection of elements in probability sampling introduces the possibility of obtaining estimates that deviate markedly from the parameter(s) of interest. Fortunately, there exist numerous design features that dampen the magnitude of sample-to-sample variation in estimates and reduce the likelihood of large deviations. Broadly, the accuracy of an estimator can be improved by applying designs that enhance the dispersion of sample elements across the population or that exploit pertinent auxiliary information on the structure of that population.

Simple random sampling (SRS) is among the most basic of probability sampling designs. From a list frame, a fixed number n of independent selections are made with all elements having identical inclusion probabilities. Whether elements are selected with or without replacement, SRS results in every combination of n elements being drawn with the same frequency. Without replacement, SRS carries the advantage that, on average, individual samples contain a larger number of

distinct population elements. Therefore, more information about the population is collected than when element-replacement is permitted, and there is less sample-to-sample variation among parameter estimates.

By eliminating the independence of selections, systematic sampling provides a direct means of drawing dispersed sets of elements. With a systematic probability sampling design, one element is randomly selected from the frame, and then all elements that are separated from this initial selection by a fixed sampling interval are added to the sample. A sample of citizens voting at one location, for example, could be drawn by rolling a die to select one of the first six voters and then subsequently interviewing every sixth voter to exit the polling station. Systematic sampling generally ensures that all elements have equal inclusion probabilities but, at the same time, renders observable only those combinations of elements that are congruent with the sampling interval. Systematic designs are particularly efficient when the sampling interval separates selected elements along a population gradient, be it a natural gradient or one artificially imposed by ordering the frame. By ensuring that every possible sample spans such a gradient, a systematic design reduces variation among estimates and generally improves precision relative to SRS. Unfortunately, because sample elements are not selected independently, it is difficult to assess the precision of estimates if only a single systematic sample is collected.

If prior information exists on natural classifications of the elements of a population, a stratified sampling design can be employed. Such a design divides the population into an exhaustive set of disjoint strata and specifies the collection of mutually independent probability samples from each. Thus, pupils in a school district or trees in a forest stand might be stratified into elementary and secondary students, or into conifer and deciduous species, prior to sampling. As sample elements are necessarily drawn from each stratum, stratified designs permit estimation of stratum-level parameters while ensuring a broad level of coverage across the population as a whole. Moreover, if a significant proportion of the variability in the attribute of interest (e.g., student attendance rate or tree biomass) is due to differences among strata, stratification can lead to large gains in precision relative to SRS.

Stratified sampling designs often vary the inclusion probabilities across strata in order to sample larger, more variable, or more important strata with higher intensity. This concept is carried further by many unequal probability sampling designs, such as Poisson sampling and list sampling. These designs are most effective when the inclusion probability of each

element can be made approximately proportional to the magnitude of the attribute of interest. Often this is achieved by making the inclusion probabilities proportional to a readily available auxiliary variable that is in turn positively correlated with the attribute of interest. Thus, if interest centers on total research expenditures in a manufacturing sector, firms with a larger number of employees might be assigned larger inclusion probabilities; if total tree biomass in a stand is of interest, trees with large basal diameters might be assigned larger inclusion probabilities. The attribute measurements taken on the sampled elements can be weighted by their respective inclusion probabilities to secure unbiased estimation. Additionally, if the inclusion probabilities have been judiciously chosen, the probability-weighted attribute measurements can be appreciably less variable than the raw attribute scores, which can lead to substantially less variation among estimates than is seen under SRS.

One area of active research in probability sampling is the incorporation of statistical models into sample selection and estimation strategies. In many cases, this offers the potential to improve accuracy without sacrificing the objectivity of the probability sampling design as the basis for inference. Of course, in many applications, statistical models can be used to great effect as a basis for inference, but the validity of inferences so drawn then rest on the veracity of the presumed model rather than on the sample selection process itself.

depends on the events having met certain conditions. Thus, each law is accompanied by a list of what, if anything, must be assumed about the events in question for the law to hold. There is no specific number or set of equations defined by the term *laws of probability*. A list that covers probabilistic relationships that are most often of interest, such as the probability that at least one of two events occurs, or the probability that two events occur together, is given here. Probability laws are employed frequently in quantitative research, as they are an essential piece of the foundation upon which much of the field of statistics—and all statistical inference—is built.

Experiments, Outcome Sets, and Events

Probability laws are defined in the context of an *experiment* whose outcome is due to chance. The set of all possible outcomes for a particular experiment is the *outcome set*, or *sample space*, and is commonly denoted by Ω . An *event* is any subset of the outcome set Ω . Examples of experiments and their corresponding outcome sets are given below; each is accompanied by two event examples.

Experiment 1: Flip a coin and record which side, heads or tails, lands face up. In this case, the sample space consists of two elements: heads and tails. The outcome set could be denoted $\Omega = \{H, T\}$. If E_1 represents the subset $\{T\}$ of Ω , then E_1 is the event that a tail is flipped. If E_2 represents the subset $\{H\}$ of Ω , then E_2 is the event that a head is flipped.

Experiment 2: Flip a coin twice and record the side that lands face up in the first flip, and then in the second flip. Here, there are four possible outcomes: $\Omega = \{HH, HT, TH, TT\}$, where, for example, TH represents the outcome where a tail is observed on the first flip and a head on the second. If $E_1 = \{HH, TT\}$, then E_1 denotes the event that the two flips are in agreement. If $E_2 = \{TH, TT\}$, then E_2 denotes the event that a tail was flipped first.

Experiment 3: Flip a coin until the first head appears. In this case, the number of outcomes is infinite, but countable: $\Omega = \{H, TH, TTH, TTTH, \dots\}$. If E_1 is the event that at most two tails are observed before the first head, then E_1 is equal to the subset $\{H, TH, TTH\}$ of Ω . If E_2 is the event that exactly three tails are observed, then $E_2 = \{TTTH\}$.

Experiment 4: Roll a six-sided die so that it comes to rest on a table. Record the number of spots facing up. In this example, the outcome set is numeric: $\Omega = \{1, 2, 3, 4, 5, 6\}$. If E_1 is the event that a number greater than 2 is rolled, then $E_1 = \{3, 4, 5, 6\}$. If E_2 is the event that an even number is rolled, then $E_2 = \{2, 4, 6\}$.

PROBABILITY, LAWS OF

The laws of probability are a collection of equations that define probabilistic relationships among events. The validity of each equation, or probability law, often

Experiment 5: Roll a six-sided die so that it comes to rest on a round table. Record the distance from the die to the center of the table. If r is the radius of the table, then the experimental outcome must be a real number from 0 to r ; hence, the outcome set is infinite and uncountable: $\Omega = [0, r)$. Notice that this interval implies that a die rolling a distance r or greater from the center of the table will fall off the table (and hence be ignored as it does not fit the definition of this experiment). If E_1 is the event that the die lands closer to the center of the table than to the nearest edge, then $E_1 = [0, r/2)$. If E_2 is the event that the die lands in the outer half of the table area, then $E_2 = [(r/\sqrt{2}), r)$.

These experiments exemplify a variety of outcome set characteristics: They can be numeric or non-numeric, as well as finite, countably infinite, or uncountably infinite. Probability laws, which govern the probabilities assigned to subsets of Ω , are invariant to such outcome set distinctions.

Union, Intersection, and Disjoint Events

The *union* of two events E_1 and E_2 , denoted $E_1 \cup E_2$, is the subset of Ω such that each element of this subset is in E_1 , E_2 , or both E_1 and E_2 . Because unions of events are also subsets of Ω , event unions are themselves events. The following four expressions of event union are equivalent:

- $E_1 \cup E_2$
- the union of E_1 and E_2
- either E_1 or E_2 occurs
- at least one of E_1 or E_2 occurs.

Note that “either E_1 or E_2 occurs” includes cases where both E_1 and E_2 occur.

The *intersection* of two events E_1 and E_2 , denoted $E_1 \cap E_2$, represents only the elements of Ω common to both E_1 and E_2 . As with unions, event intersections are subsets of Ω and therefore are events themselves. The following three expressions of event intersection are equivalent:

- $E_1 \cap E_2$
- the intersection of E_1 and E_2
- both E_1 and E_2 occur.

If events E_1 and E_2 do not intersect, then these two events cannot both be observed in a single experimental outcome. In this case, E_1 and E_2 are said to be *disjoint*, or *mutually exclusive*.

In the single coin flip example, Experiment 1, the union of events E_1 and E_2 represent the entire outcome set: $E_1 \cup E_2 = \{H, T\} = \Omega$. The intersection of these two

events, however, is empty; these events are disjoint. If $\emptyset$ denotes the empty set, then $E_1 \cap E_2 = \emptyset$.

In the double coin flip example, Experiment 2, the union of events E_1 and E_2 is a three-element subset of Ω : $E_1 \cup E_2 = \{HH, TH, TT\}$. The intersection of these two events is a single outcome: $E_1 \cap E_2 = \{HT\}$. Because this intersection is not empty, E_1 and E_2 are not disjoint.

The union of events E_1 and E_2 in the first head coin flip example, Experiment 3, contains four outcomes: $E_1 \cup E_2 = \{H, TH, TTH, TTTH\}$. Because no elements of E_1 are common to E_2 , the intersection of these two events is empty and the events are disjoint: $E_1 \cap E_2 = \emptyset$.

In the spot-recording die example, Experiment 5, rolling a number greater than $2(E_1)$ or rolling an even number (E_2) is an event composed of four outcomes: $E_1 \cup E_2 = \{3, 4, 5, 6\}$. These events are not disjoint, as their intersection is not empty: $E_1 \cap E_2 = \{4, 6\}$.

In the distance-recording die example, Experiment 5, rolling closer to the center of the table than to the nearest edge (E_1) or rolling in the outer half of the table area (E_2) is an event composed of two nonoverlapping intervals: $E_1 \cup E_2 = \{[0, r/2), [(r/\sqrt{2}), r)\}$. Because there are no elements of Ω common to both E_1 and E_2 , these events are disjoint: $E_1 \cap E_2 = \emptyset$.

Three Axioms of Probability

Suppose a particular experiment is performed many, many times. Then the *probability* of an event E , denoted $P(E)$, is the proportion of those times that this event would be expected to occur. In other words, the probability of an event is the expected long-run relative frequency of the event. Not only do the laws of probability govern the values $P(E)$ may assume, they also provide the means to equivalently express probabilities involving multiple events.

The following three probability laws—called *axioms* because they are sufficiently self-evident—provide the basis for proving all other probability laws:

1. $P(E) \geq 0$ for any event E .
2. $P(\Omega) = 1$.
3. $P(E_1 \cup E_2) = P(E_1) + P(E_2)$, provided E_1 and E_2 are disjoint.

The first law states that probabilities can never be negative. This follows directly from the expected long-run relative frequency interpretation of probability. Probabilities can, however, be zero. Events having zero probability can never be observed as an experimental outcome. Events having probability one, on the other hand, are always observed on *every* experimental outcome (this also follows directly from the expected

long-run relative frequency interpretation of probability). Because Ω is composed of all possible experimental outcomes, some element of Ω must be observed every time the experiment is performed. Hence, $P(\Omega) = 1$. Furthermore, the combination of Axioms 1 and 2 reveal that, for any event E , the probability of this event must be contained in the interval $[0, 1]$.

The third axiom, or law, is valid as long as events E_1 and E_2 are disjoint. Provided they are disjoint, the probability of the union of these two events is equal to the sum of their individual probabilities. This follows from the expected long-run relative frequency probability interpretation: The proportion of times E_1 or E_2 occurs is equal to the proportion of times E_1 occurs, plus the proportion of times E_2 occurs, assuming these events cannot happen simultaneously. This axiom also implies that the union of any number of disjoint events has probability equal to the sum of the individual event probabilities.

Complementary Events and Partitions

For any event E , define the *complement* of E , denoted E^C , to be all elements of Ω not contained in E . Notice E^C is a subset of Ω , and therefore is an event. This implies that both of the following are true:

- $E \cup E^C = \Omega$, and
- $E \cap E^C = \emptyset$.

Any collection of two or more disjoint events (all pairwise intersections are empty) whose union represents the entire outcome set is called a *partition* of Ω . Thus, an event and its complement will always form a partition of Ω . An example of a three-event partition can be found using the spot-recording die example, Experiment 4, and letting E_3 be the event a 2 is rolled, and E_4 be the event a 1 is rolled. Then, having defined $E_1 = \{3, 4, 5, 6\}$, the events E_1, E_3 , and E_4 form a partition of Ω : Any pair of these three events is disjoint, and $E_1 \cup E_3 \cup E_4 = \Omega$.

Complementary Event Probability

The probability of E^C is found easily by using probability Axioms 2 and 3. By definition of complementary events, $\Omega = E \cup E^C$. The probabilities of these identical events are also identical: $P(\Omega) = P(E \cup E^C)$. Axiom 2 allows us to express $P(\Omega)$ as 1, giving $1 = P(E \cup E^C)$. Axiom 3 allows us to express $P(E \cup E^C)$ as $P(E) + P(E^C)$ because E and E^C are disjoint. This gives $1 = P(E) + P(E^C)$, and thus $P(E^C) = 1 - P(E)$ for any event E . Sometimes referred to as the *complementary law of probability*, this rule states that the chance an event does not

occur is equivalent to one minus the probability that the event does occur.

General Probability of Event Union

The general formula for the probability that E_1 or E_2 occurs is

$$P(E_1 \cup E_2) = P(E_1) + P(E_2) - P(E_1 \cap E_2)$$

for any event E_1 and E_2 .

This general rule, sometimes referred to as the *additive law of probability*, can be proven using Axiom 3 in conjunction with the complementary law of probability. Notice that Axiom 3 is a special case of this additive law: If E_1 and E_2 are disjoint, then their intersection is empty and has probability zero.

Event Probability in Terms of a Partition

Suppose $E_1, E_2, \dots, E_k$ represents a k -event partition of Ω . Then, for any event F , the events $F \cap E_1$ and $F \cap E_2$ are disjoint, as the part of F that overlaps with E_1 must have nothing in common with the part of F that overlaps E_2 (E_1 and E_2 are, by definition of a partition, disjoint). Hence any two of the events $F \cap E_1, F \cap E_2, \dots, F \cap E_k$ are disjoint. Furthermore, the union of these events must equal F : $F = (F \cap E_1) \cup (F \cap E_2) \cup \dots \cup (F \cap E_k)$, because $E_1 \cup E_2 \cup \dots \cup E_k = \Omega$. This allows for a rule that expresses the probability of an event F in terms of a partition:

$$P(F) = P(F \cap E_1) + P(F \cap E_2) + \dots + P(F \cap E_k)$$

for any event F ,

provided the events $E_1, E_2, \dots, E_k$ form a partition of Ω . There is no commonly used nomenclature for this probability law.

Conditional Probability

Conditional probability asks the question: If an experiment is performed and it is only known that event E has occurred, then what is the chance that event F has also occurred? The common notation for a conditional probability is $P(F|E)$, and is read as “the (conditional) probability of F , given E .”

The key to computing conditional probabilities is recognizing that because event E is known to have occurred, the outcome set for that particular experiment can be *reduced* to the subset E . If no elements of F are contained within E , and E has occurred, then F cannot have occurred. Thus, the conditional probability of F , given E , is always zero when F and E are disjoint. If the intersection of F and E is not empty, then

some elements of E are also elements of F . The probability of these common elements, divided by the probability of E itself, gives the *law of conditional probability*:

$$P(F|E) = \frac{P(F \cap E)}{P(E)} \text{ for any event } F,$$

and any event E where $P(E) > 0$.

In the spot-recording die example, Experiment 4, suppose the die is rolled and it is known only that an even number of spots is showing (event E_2 is known to have occurred). Then the conditional probability that the roll is a 2 (event E_3) is given by

$$\begin{aligned} P(E_3|E_2) &= \frac{P(E_3 \cap E_2)}{P(E_2)} = \frac{P(\{2\} \cap \{2,4,6\})}{P(\{2,4,6\})} \\ &= \frac{P(\{2\})}{P(\{2,4,6\})}. \end{aligned}$$

Thus, the chance of having rolled a 2, given that the roll was even, is the probability of rolling a 2 divided by the probability of rolling an even number. If we assume that all six faces of the die are equally likely (probability $1/6$ each), then this probability is $1/6$ divided by $3/6$, which equals $1/3$. Note that without knowledge that an even number was rolled, the probability of a 2 is $1/6$. With knowledge that E_2 has occurred, however, the probability of rolling a 2 is updated to $1/3$.

Consider the slight change to this example where the roll is still known to have been even, but now the conditional probability of rolling greater than 2 (event E_1) is of interest. The conditional law of probability gives

$$\begin{aligned} P(E_1|E_2) &= \frac{P(E_1 \cap E_2)}{P(E_2)} \\ &= \frac{P(\{3,4,5,6\} \cap \{2,4,6\})}{P(\{2,4,6\})} \\ &= \frac{P(\{4,6\})}{P(\{2,4,6\})}. \end{aligned}$$

Assuming the die to be fair, the probability of rolling a 4 or 6 is $2/6$, whereas the probability of rolling an even number is $3/6$. Hence, the chance of rolling greater than 2, given that an even number was rolled, is $2/6$ times $6/3$, which equals $2/3$. Note, then, that the chance of rolling greater than 2 without knowledge of rolling an even number, is also $2/3$. This example can be expressed symbolically as $P(E_1|E_2) = P(E_1) = 2/3$.

Independence

In cases where $P(E_1|E_2) = P(E_1)$, the probability that E_1 has occurred does not change with knowledge that E_2 has occurred. Whenever a pair of events exhibits such a relationship, they are said to be *independent*. To check whether events are independent, it is common to calculate the probabilities on both sides of this equation, or its equivalent counterpart $P(E_1|E_2) = P(E_2)$, and check for equality. If equality does not hold, then the events are said to be dependent.

Another equivalent, and more common, definition of independent events can be found by multiplying both sides of $P(E_1|E_2) = P(E_1)$ by $P(E_2)$. Then use the conditional probability law to recognize the resulting left-hand side as $P(E_1 \cap E_2)$. This gives the following definition of independent events:

If events E_1 and E_2 satisfy

$$P(E_1 \cap E_2) = P(E_1)P(E_2),$$

then E_1 and E_2 are independent events:

The converse of this statement also holds, and is sometimes referred to as the *multiplicative law of probability*:

$$P(E_1 \cap E_2) = P(E_1)P(E_2) \text{ when } E_1 \text{ and } E_2 \text{ are independent.}$$

This law is relied upon frequently, not necessarily to check for independence, but rather to calculate the probability of event intersections upon *assuming* independence. Furthermore, if three events are to be independent, then not only must the probability of their three-way intersection equal the product of their three individual probabilities, but the intersection probability of any pair of events must equal the product of the corresponding two individual probabilities.

Note that the term *independent* should not be confused with *disjoint*. The probability of disjoint events occurring simultaneously is zero, whereas the probability of independent events occurring simultaneously is—for all cases of practical relevance—strictly positive.

Law of Total Probability

The law of total probability uses the conditional probability law to modify the probability of an event F in terms of a partition. If $E_1, E_2, \dots, E_k$ form a partition of Ω , then $P(F \cap E_1)$ can be equivalently expressed as $P(F|E_1)P(E_1)$ by the conditional probability law. This gives the following equation

$$P(F) = P(F|E_1)P(E_1) + P(F|E_2)P(E_2) + \dots + P(F|E_k)P(E_k),$$

which is commonly known as the *law of total probability*. This law is useful in situations where the probability of an event of interest (F) is known within each partition of the outcome set, but not overall. For example, consider a population of individuals where 20% are considered to be young, 50% are considered to be middle-aged, and the remaining 30% are considered to be senior. Suppose it is known that 10% of those who are young have condition F , 30% of those who are middle-aged have condition F , and 70% of those who are senior have condition F . The probability of selecting an individual at random from this population (put their names in a hat and draw one, for example) who has condition F is given by the law of total probability. Letting E_1 be the event that a youth is selected, E_2 be the event that a middle-aged individual is selected, and E_3 be the event that a senior is selected gives

$$\begin{aligned} P(F) &= P(F | E_1)P(E_1) + P(F | E_2)P(E_2) + \\ &\quad P(F | E_3)P(E_3) \\ &= (0.1)(0.2) + (0.3)(0.5) + (0.7)(0.3) \\ &= 0.38. \end{aligned}$$

Thus, there is a 38% chance that an individual selected from this population will have condition F . Equivalently, 38 out of every 100 individuals selected (with replacement) from this population are expected to have condition F .

Other Laws of Probability

Any equality or inequality regarding the probability of an event (or events) can be considered a law of probability, provided it can be derived from the three probability axioms. If, for example, event E_1 is a subset of event E_2 , then the relationship $P(E_1) \leq P(E_2)$ must hold. The laws presented previously, however, can be considered among those of most practical use.

Finally, it should be cautioned that events whose probabilities satisfy probability laws are *not* necessarily events whose probabilities are realistic. One may decide, in the spot-recording die example, Experiment 4, that the probabilities associated with rolling numbers 1 through 5 are all 0.1, while the probability associated with rolling a 6 is 0.5. Such an assignment of probabilities (or probability model) is entirely legitimate according to the laws of probability. This assignment would not, however, describe well the outcomes of this experiment if the die were fair (or biased in any way other than what these probabilities represent). Although probability laws can be used to calculate correct event probabilities, it is up to the researcher to

ensure that the components used for such calculations are realistic.

“PROBABLE ERROR OF A MEAN, THE”

Initially appreciated by only a handful of brewers and statisticians, “The Probable Error of a Mean” is now, 100 years later, universally acclaimed as a classic by statisticians and behavioral scientists alike. Written by William Sealy Gosset under the pseudonym “Student,” its publication paved the way for the statistical era that continues today, one focused on how best to draw inferences about large populations from small samples of data.

Gosset and “Student”

Schooled in mathematics and chemistry, Gosset was hired by Arthur Guinness, Son, & Co., Ltd. to apply recent innovations in the field of statistics to the business of brewing beer. As a brewer, Gosset analyzed how agricultural and brewing parameters (e.g., the type of barley used) affected crop yields and, in his words, the “behavior of beer.” Because of the cost and time associated with growing crops and brewing beer, Gosset and his fellow “experimental” brewers could not afford to gather the large amounts of data typically gathered by statisticians of their era. Statisticians, however, had not yet developed accurate inferential methods for working with small samples of data, requiring Gosset to develop methods of his own. With the approval of his employer, Gosset spent a year (1906–1907) in Karl Pearson’s

biometric laboratory, developing “The Probable Error of a Mean” as well as “Probable Error of a Correlation Coefficient.”

The most immediately striking aspect of “The Probable Error of a Mean” is its pseudonymous author: “Student.” Why would a statistician require anonymity? The answer to this question came publicly in 1930, when fellow statistician Harold Hotelling revealed that “Student” was Gosset, and that his anonymity came at the request of his employer, a “large Dublin Brewery.” At the time, Guinness considered its use of statistics a trade secret and forbade its employees from publishing their work. Only after negotiations with his supervisors was Gosset able to publish his work, agreeing to neither use his real name nor publish proprietary data.

The Problem: Estimating Sampling Error

As its title implies, “The Probable Error of a Mean” focuses primarily on determining the likelihood that a sample mean approximates the mean of the population from which it was drawn. The “probable error” of a mean, like its standard error, is a specific estimate of the dispersion of its sampling distribution and was used commonly at the start of the 20th century. Estimating this dispersion was then, and remains today, a foundational step of statistical inference: To draw an inference about a population parameter from a sampled mean (or, in the case of null hypothesis significance testing, infer the probability that a certain population would yield a sampled mean as extreme as the obtained value), one must first specify the sampling distribution of the mean. The Central Limit Theorem provides the basis for parametrically specifying this sampling distribution but does so in terms of population variance. In nearly all research, however, both population mean and variance are unknown. To specify the sampling distribution of the mean, therefore, researchers must use the sample variance.

Gosset confronted this problem with using sample variance to estimate the sampling distribution of the mean, namely, that there is error associated with sample variance. And because the sampling distribution of the variance is positively skewed, this error is more likely to result in the underestimation than the overestimation of population variance (even when using an unbiased estimator of population variance). Furthermore, this error, like the error associated with sampled means, increases as sample size decreases, presenting a particular (and arguably exclusive) problem for small sample researchers such as Gosset. To draw inferences about population means from sampled data, Gosset could not—as large-sample researchers did—simply calculate a standard z statistic and rely on a unit normal table to find the corresponding p values. The unit normal table does not

account for either the estimation of population variance or the fact that the error in this estimate depends on sample size. This limitation inspired Gosset to write “The Probable Error of a Mean” in a self-described effort to (a) determine at what point sample sizes become so small that the above method of normal approximation becomes invalid and (b) develop a set of valid probability tables for small sample sizes.

The Solution: z

To accomplish these twin goals, Gosset derived the sampling distribution of a new statistic he called z . He defined z as the deviation of the mean of a sample ($\bar{X}$) from the mean of a population (μ) divided by the standard deviation of the sample (s), or $(\bar{X} - \mu) / s$. In his original paper, Gosset calculated s with the denominator n (leading to a biased estimate of population variance, s^2) rather than the unbiased $n - 1$, likely in response to Pearson’s famous attitude that “only naughty brewers take n so small that the difference is not of the order of the probable error!” To determine the sampling distribution of z , Gosset first needed to determine the sampling distribution of s . To do so, he derived the first four moments of s^2 , which allowed him to make an informed guess concerning its distribution (and the distribution of s). Next, he demonstrated that $\bar{X}$ and s were uncorrelated, presumably in an effort to show their independence. This independence—in conjunction with equations to describe the distribution of s —allowed Gosset to derive the distribution of z .

This first portion of “The Probable Error of a Mean” is noteworthy for its speculative, incomplete, and yet ultimately correct conclusions. Gosset failed to offer a formal mathematical derivation for the sampling distribution of s , despite the fact that, unbeknownst to him, such a proof had been published 30 years earlier by the German statistician Friedrich Robert Helmert. Nor was Gosset able to prove that the sampling distributions of s^2 and $\bar{X}$ were completely independent of each other. Nevertheless, Gosset was correct on both counts, as well as his ensuing derivation of the sampling distribution of z , leading many to note that his statistical intuition more than compensated for his admitted mathematical shortcomings.

Pioneering Use of Simulation

“The Probable Error of a Mean” documents more than Gosset’s informed speculation, however; it presents one of the first examples of simulation in the field of statistics. Gosset used simulation to estimate the sampling distribution of z nonparametrically, and then compared this result to his parametrically derived distribution.

Concordance between the two sampling distributions, he argued, would confirm the validity of his parametric equations.

To conduct his simulation, he relied on a biometric database of height and finger measurements collected by British police from 3,000 incarcerated criminals; this database served as his statistical population. Gosset randomly ordered the data—written individually on pieces of cardboard—then segregated them into 750 samples of 4 measurements each (i.e., $n = 4$). For every sample, he calculated z for height and finger length, then compared these two z distributions with the curves he expected from his parametric equations. In both cases, the empirical and theoretical distributions did not differ significantly, thus offering evidence that Gosset’s preceding equations were correct.

Tables and Examples

Gosset dedicated the final portion of “The Probable Error of a Mean” to tabled probability values for z and illustrative examples of their implementation. To construct the tables, he integrated over the z distributions (for sample sizes of 4–10) to calculate the probability of obtaining certain z values or smaller. For purposes of comparison, he also provided the p values obtained via the normal approximation to reveal the degree of error in such approximation. The cumbersome nature of these calculations deterred Gosset from providing a more extensive table.

In further testament to his applied perspective, Gosset concluded the main text of “The Probable Error of a Mean” by applying his statistical innovation to four sets of actual experimental data. In the first and most famous example, Gosset analyzed data from a 1904 experiment that examined the soporific effects of two different drugs. In this experiment, researchers had measured how long patients ($n = 15$) slept after treatment with each of two drugs and a drug-free baseline. To determine whether the drugs helped patients sleep, Gosset tested the mean change in sleep for each of the drug conditions (compared to the baseline) against a null (i.e., zero) population mean. To test whether one drug was more effective than the other drug, he tested the mean difference in their change values against a null population mean. All three of these tests—as well as the tests used in the three subsequent examples—correspond to modern-day one-sample t tests (or equivalent paired t tests).

Postscript: From z to t

With few exceptions over nearly 20 years following its publication, “The Probable Error of a Mean” was

neither celebrated nor appreciated. In fact, when providing an expanded copy of the Student z tables to then little-known statistician Ronald Fisher in 1922, Gosset remarked that Fisher was “the only man that’s ever likely to use them!” Fisher ultimately disproved this gloomy prediction by championing Gosset’s work and literally transforming it into a foundation of modern statistical practice.

Fisher’s contribution to Gosset’s statistics was threefold. First, in 1912 and at the young age of 22, he used complex n -dimensional geometry (that neither Gosset nor Pearson could understand) to prove Gosset’s equations for the z distribution. Second, he extended and embedded Gosset’s work into a unified framework for testing the significance of means, mean differences, correlation coefficients, and regression coefficients. In the process of achieving this unified framework (based centrally on the concept of degrees of freedom), Fisher made his third contribution to Gosset’s work: He multiplied z by $\sqrt{n-1}$, transforming it into the famous t statistic that now inhabits every introductory statistics textbook.

During Fisher’s popularization, revision, and extension of the work featured in “The Probable Error of a Mean,” he corresponded closely with Gosset. In fact, Gosset is responsible for naming the t statistic, as well as calculating a set of probability tables for the new t distributions. Despite Gosset’s view of himself as a humble brewer, Fisher considered him a statistical pioneer whose work had not yet received the recognition it deserved.

Historical Impact

The world of research has changed greatly in a century, from a time when only “naughty brewers” gathered data from sample sizes not measured in hundreds, to an era characterized by small sample research. “The Probable Error of a Mean” marked the beginning of serious statistical inquiry into small sample inference, and its contents today underlie behavioral science’s most frequently used statistical tests. Gosset’s efforts to derive an exact test of statistical significance for such samples (as opposed to one based on a normal approximation) may have lacked mathematical completeness, but their relevance, correctness, and timeliness shaped scientific history.

PROPENSITY SCORE ANALYSIS

Propensity score analysis is a technique for estimating the causal effect of a treatment in an observational study. Although randomized experiments are the ideal method for estimating the causal effect of a treatment—because randomization ensures that, on average, the distribution of both observed and unobserved characteristics are the same for treated and untreated units—there are many cases where randomized experiments are unethical or impractical. In an observational study, unlike in a randomized experiment, the researcher has no control over treatment assignment. As a result, due to self-selection into treatment or other nonrandom aspects of the treatment assignment, there may be systematic differences between the treated and control groups that can bias the estimate of treatment effects. Using propensity scores to match treated units to similar control units is one way to adjust for observed differences between the two groups and thereby reduce this selection bias in the treatment effect estimate. Bias may not be completely eliminated because propensity score analysis will not adjust for unobserved differences between the two groups, except to the extent that observed variables are correlated with these unobserved variables; however, this is a limitation of any nonrandomized study.

This entry describes the theory underlying this analysis. Next, the entry presents the steps involved in implementing propensity score analysis. The entry concludes with a brief discussion of alternate uses for propensity scores.

Underlying Theory

Formally, the propensity score is defined as the conditional probability of receiving treatment given a set of observed covariates. For simplicity, treatment will be assumed to be a binary variable (i.e., treatment or control). The majority of propensity score research addresses this binary treatment case; however, the propensity score method has been extended to treatments with multiple doses. The propensity score is a one-number summary of the multivariate information in the covariates that are related to treatment assignment. More specifically, the propensity score is a balancing score in the sense that matching on the propensity score creates pairs or subclasses within which the distribution of observed covariates is the same, on average, for both treated and control groups. In other words, the covariate distributions are "balanced" between the treated and control groups within these subclasses. Under two key assumptions—strongly ignorable treatment assignment and stable unit treatment value assumption (SUTVA)—an unbiased estimate of the average treatment effect at a specific propensity score value is given by the difference between the treated and control means for all units with that value of the propensity score. Averaging these differences across all propensity score values in the population yields an average overall treatment effect. The strongly ignorable treatment assumption implies that each unit has a non-zero probability of receiving treatment and that all relevant covariates have been included in the propensity score model so that treatment assignment is unconfounded with the covariates (sometimes referred to as "unconfoundedness" or "no hidden bias" or "selection on observables"). The SUTVA assumption implies that there is only one version of each treatment for each unit and that the treatment assignment of one unit does not affect the outcome of any other units ("no interference between units").

Of course, true propensity scores are never known and must be estimated. Estimated propensity scores can be used to create matched pairs or groups of treated and control units with similar propensity score values. Estimates of treatment effects are obtained by comparing treated and control units within these matched pairs or groups.

Implementation of a Propensity Score Analysis

Select the Covariates

In order to adjust for all possible systematic differences between the treated and control groups, common advice is to include as many covariates as possible in the propensity score model. More specifically, any covariates that are thought to be related to treatment assignment and the outcomes of interest should be included. Care must be taken, however, to include only variables that are not affected by treatment assignment. Including variables that are affected by the treatment can bias the treatment effect estimates.

Measure the Initial Imbalance in the Covariates

Calculating a baseline measure of covariate imbalance is useful as a benchmark to judge how well the propensity score matching method improved balance. Many researchers use significance tests to test for balance in the covariates. For example, a two-sample t test can be used to test the difference in the mean of a continuous covariate between the treated and control groups, and a two-sample test of proportions can be used for a binary covariate. However, this has been recently criticized as being sensitive to changes not only in balance but also in sample size. For example, some observations may be dropped during the matching process if good matches cannot be found for them, thereby reducing the sample size and power of the test. Although the best way to measure balance is still being debated in the statistical literature, one of the currently suggested alternatives to significance tests is to measure the standardized difference between the treated and control groups with a difference of .1 (as a rule of thumb) indicating substantial imbalance. Different versions of the formula for calculating the absolute standardized difference appear in the literature. Two versions of the formula for continuous covariates are

$$d = \frac{(\bar{X}_{\text{treatment}} - \bar{X}_{\text{control}})}{\sqrt{\frac{S_{\text{treatment}}^2 + S_{\text{control}}^2}{2}}}$$

or

$$d = \frac{(\bar{X}_{\text{treatment}} - \bar{X}_{\text{control}})}{S_{\text{treatment}}}$$

Note that the key features of standardized difference (which is true for both formulas) are that it does not depend on the unit of measurement and, unlike a t statistic, is not influenced by sample size.

Estimate the Propensity Score

The most common method to estimate the propensity score is via logistic regression, but it is possible to use other methods, such as probit regression or even classification trees. Assuming a binary treatment, the logistic regression propensity score model can be specified as

$$\log\left(\frac{P_i}{1-P_i}\right) = \alpha + \beta X_i,$$

where P_i is the probability that unit i receives treatment (as opposed to control) and X_i is a vector of covariates and any relevant interactions thereof. This model yields $\hat{P}_i$, the estimated propensity score, for each unit. The quality of the estimated propensity score model should be judged in terms of the balance that is achieved after matching on the propensity scores. The usual goodness-of-fit measures (such as the area under the Receiver Operating Curve) and the statistical significance of the coefficients are not useful here. Similarly, because the goal of the propensity score model is to produce balanced subclasses of treated and control units, it is not necessary to search for a parsimonious model (unless a small sample size forces the analyst to limit the number of covariates in the propensity score model).

Check for Overlap in the Propensity Score Distributions

A first step in matching or subclassifying on the estimated propensity score is to confirm that there is an adequate overlap in the distribution of estimated propensity scores (or “common support”) for treated and control units to make reliable treatment effect estimates. This can be done by graphing overlapping histograms or by tallying sample sizes separately by treatment group within quintiles (for example) of the estimated propensity scores. If there is no overlap or minimal overlap in the distribution of propensity scores across treatment groups, then any estimates of the treatment effect will rely on model extrapolation. For example, in the extreme (and simplistic) case that all treated units are female and all control units are male, no treatment effect estimates can be made without making some assumptions about the relationship between males and females and the outcome. In a less extreme case, one may find that treatment effects can be estimated only within a certain subset of the population. For example, if the estimated propensity scores for the control group range between .10 and .65, and the estimated propensity scores for the treatment group

range between .45 and .95, then one can estimate only the treatment effects for the subset of the population with estimated propensity scores between .45 and .65. In the range between .10 and .45, there are no treated units to compare to the control units, and in the range between .65 and .95, there are no control units to compare to the observed treated units. This diagnostic property of propensity scores has been cited as one of the advantages of the propensity score method over traditional methods such as linear regression.

At this point, the analyst must decide what to do with the overlap information. In some cases, the analyst may decide to restrict all further analysis to the region of propensity score overlap. In other cases, the analyst may find that there are only a few cases in the nonoverlapping tail area, and keeping them in the analysis does not adversely affect the balance in the covariates or the quality of the matches obtained.

Match or Subclassify the Estimated Propensity Score

There are many propensity score matching methods. Without going into the details of the specific implementation of any particular matching method, the main matching issues are discussed here. User-written matching programs are available for Stata, R, and SAS.

Size of the Matched Groups. Nearest neighbor matching selects k matched controls for each treated unit. The simplest and most common variation of this method uses $k = 1$ for matched pairs of treated and control units. Values of k larger than 1 can be used when there are large numbers of control units relative to treated units. Also, k can vary across treated units. Matching each treated unit to multiple control units can reduce sampling variance in the treatment effect estimates because of the larger matched sample size. On the other hand, because these extra matches are further away from the treated unit than the first closest match (unless the controls have the exact same covariate values), using multiple controls for each treated unit will increase the bias in our treatment effect estimates. Using multiple controls can also be more costly if, for example, additional data need to be gathered from the selected matches.

Matching Algorithm. The simplest way to select matches is to sequentially select the closest control unit for each treated unit. This type of “greedy” algorithm finds different matches depending on how the treated units are sorted because matches are selected without regard as to whether the untreated unit would better serve as a match to a different treated unit yet to be encountered in the list. This may have a substantial effect on the quality of the matches when the overlap in the propensity score distributions of the treated and

control units is small, but may not have much of an effect on the matches when there is substantial overlap in the propensity score distributions. A more sophisticated “optimal” matching algorithm finds the set of matches that minimizes a global measure of distance across all matches.

Matching With or Without Replacement. In with-replacement matching, controls can be used as matches for more than one treated unit, as opposed to without-replacement matching, where each unit can be used in only one match. Matching with replacement can be useful when there are few control units that are comparable to treated units. Also, when matching with replacement, the order in which matches are found does not matter. However, when matching is done with replacement, it is possible that subsequent treatment effect estimates are based on just a small number of controls. The number of times each control is used as a match should be monitored and possibly controlled.

Matching for Key Covariates. When it is important to find matches that are particularly close on a few key covariates, propensity score matching techniques can be extended to Mahalanobis metric matching within propensity score calipers. In this method, the closest control unit, in terms of Mahalanobis distance on the key covariates, within a prespecified distance of the treated unit’s propensity score (the propensity score “caliper”) is selected as a match.

Subclassification. Subclassification forms groups of units with similar propensity scores by stratifying on values of the propensity score. For example, observations can be divided into subclasses (or strata) based on the quintiles of the estimated propensity score (this will create five groups of equal total size), or, if the effect on the treated group is of particular interest, based on the quintiles of the estimated propensity score in the treated group (this will create groups with equal numbers of treated units). Typically, five subclasses are used; however, if sample size permits, a larger number of subclasses can be used. With more subclasses, treated and control units will be more similar within each class, but using more subclasses can stretch the sample too thin, leaving some subclasses with few treated or control units, thereby decreasing the precision of the treatment effect estimates.

Subclassification has the advantage over matching of being very easy to implement (although matching software is getting easier to obtain and use) and of using all the data, whereas matching may throw away data from unmatched units. This may be a particularly important issue when generalizing to a larger population (e.g., via survey sampling weights).
